Experiments at RHIC have shown that in 200 GeV Au-Au collisions, the \( \Lambda \) and \( \bar{\Lambda} \) hyperons are produced with very small polarizations [3], almost consistent with zero. These results can be understood in terms of a model that we proposed [2]. In this work, we show how this model may be applied in such collisions, and also will discuss the relation of our results with other models, in order to explain the experimental data.

Since the discovery of significant polarization for the \( \Lambda \) particles produced in 100 GeV p-Be collisions by Bunce [3], hyperon polarization has shown to be a very challenging subject, as, at the time it was a totally surprising result. This fact, unexpected both experimentally and theoretically has been confirmed by further experiments, and this puzzle has been complicated when the polarizations of the other hyperons and antihyperons have been measured [4]-[11].

Hyperon polarization may be quite well described by parton-based models [12]-[14], but antihyperon polarization not. In [2], we proposed a model [2] that was able to describe successfully the antihyperon polarization in terms of final-state interactions that occur in the hadronic phase of such collisions, in a mechanism based in relativistic hydrodynamics.

Recently, at RHIC, in 200 GeV Au-Au collisions, the \( \Lambda \) and \( \bar{\Lambda} \) polarizations have been measured [1], as functions of the transverse momentum, in the range \( 0 < p_t < 5 \) GeV, and as functions of the pseudorapidity, in the range \(-1.5 < \eta < 1.5\). In this region, the final polarization for both particles may be considered consistent with zero. As it was suggested in [15], zero polarization in high energy nucleus-nucleus interactions, if observed, could show a signal of quark-gluon plasma formation. Some models show good results in explaining \( \Lambda \) and \( \bar{\Lambda} \) polarizations. In [18]-[20], this effect is proposed as the parsons are produced with large angular momentum, and quark polarization results from parton scattering. In [16], polarization of spin 1/2 particles for an equilibrated system is computed.

As we can see, this is a very important problem, and the objective of this letter is to study this question, showing some results that we obtained, and discussing their relations with other theoretical results. We will apply the model that we used to calculate antihyperon polarization in p-A collisions, in the study of the Au-Au collisions performed at RHIC. In [2], we have shown that significant polarization may occur considering this model. We want to investigate the effect of the final-state interactions in nucleus-nucleus collisions and if it is possible that these interactions may affect the final polarization of the produced particles. This model is based on the hydrodynamical aspects of such collisions, so, the first step is to obtain the velocity distribution of the fluid formed during the collision. Then, we will use it in order to obtain the average polarization, taking into account the \( \pi \Lambda \) and \( \pi \bar{\Lambda} \) final interactions.

In the hydrodynamical picture, in the collision of two high-energy particles, the large amount of energy localized in a very small volume produces a fluid, that expands and then produces the final particles, what may be understood by the freeze-out mechanism. We will suppose a parametrization of the velocity distribution of such fluid given by the expression

\[
\frac{d\omega^0 dp}{d^3 u} = A \left[ e^{-\beta(\alpha-\alpha_0)^2} + e^{-\beta(\alpha+\alpha_0)^2} \right] e^{-\beta \xi^2},
\]

that is written in terms of its longitudinal \((\alpha)\) and transversal \((\xi)\) rapidities. That means that the formed fluid expands in the the incident nuclei direction \((\alpha)\), and also in the transverse direction \((\xi)\). This kind of velocity distribution has shown to describe correctly the production of particles in many other systems [21], [22]. We may visualize this fluid geometrically, in a first approximation, as an hot expanding cylinder. The constants \(\beta\), \(\beta_1\) and \(\alpha_0\) are parameters that describe the shape of this distribution, and are determined by calculating the distributions of the produced particles, and, comparing them with the RHIC experimental data for the transverse momentum \(p_t\) [23] and pseudorapidity \((\eta)\) distributions [24].

This objective may be achieved, making a convolution of the fluid velocity distribution [1], with the particles distribution, inside these fluid elements, that may be considered a Bose distribution as most of the produced particles are pions. We will consider

\[
\frac{dN}{dp_0} = \frac{N_0}{\exp(E_0/T) - 1}
\]

with the temperature \(T \sim m_\pi\), and \(p_0\) and \(E_0\) are the momentum and energy of the pions inside one fluid element.
So, the observed distributions of particles are given by
\[
E \frac{dN}{d\vec{p}} = C \int \left[ e^{-\beta(\alpha - \alpha_0)^2} + e^{-\beta(\alpha + \alpha_0)^2} \right] e^{-\beta t \xi^2} \times \frac{E_0(\alpha, \xi, \phi)}{\exp(E_0(\alpha, \xi, \phi)/T) - 1} \sinh \xi \cosh \xi d\alpha d\xi d\phi,
\]
where $\phi$ is the azimuthal angle. The results of the particles distributions resulting from eq. (4) are shown in Figures 1 and 2. We obtained a very good description of $d\sigma/d\eta$ for all centralities (Fig. 1), and for the $p_t$ distribution (Fig. 2), the results are very good for $p_t < 6$ GeV. For $p_t > 6$ GeV, a small discrepancy may be noticed, and it increases with $p_t$. This fact is not a problem for the present work, as in the experimental data for polarization, the values of $p_t$ investigated are below this value. This problem shows that other processes become important at large $p_t$, such as the hard scattering ones. A way to improve the results is to insert an extra term, depending on the transverse rapidity of the fluid $\xi$, in eq. (4), what represents alterations in the equation of state. For simplicity, it will not be done in this paper.

![Figure 1](image1.png)

**FIG. 1:** Distributions $dN/d\eta$, for many centralities. From the top, 0-5%, 5-10%, 10-20%, 20-30%, 30-40%, 40-50%. We compare our results (solid lines), with the experimental data from [24] (points).

![Figure 2](image2.png)

**FIG. 2:** Comparison of the calculated distribution $dN/d^3p$ as function of $p_t$ with the experimental data from [23].

The parameters obtained are $\beta=0.14$, $\beta_t=3.2$ and $\alpha_0$ in the range 1.5-1.75, varying with the centrality, as it can be
seen in Table I. We can observe that $\beta$ and $\beta_t$ do not seem to have any dependence on the centrality.

| Centrality | $\beta$ | $\beta_t$ | $\alpha_0$ |
|------------|--------|-----------|-----------|
| 0-5%       | 0.14   | 3.2       | 1.50      |
| 5-10%      | 0.14   | 3.2       | 1.56      |
| 10-20%     | 0.14   | 3.2       | 1.62      |
| 20-30%     | 0.14   | 3.2       | 1.67      |
| 30-40%     | 0.14   | 3.2       | 1.70      |
| 40-50%     | 0.14   | 3.2       | 1.75      |

Observing these results, one may see that the fluid parametrization, with the velocities distributions given by (1), is very reasonable and describes quite well the experimental data in the region of our interest. So, considering this description, we may calculate the polarization of a hyperon (or antihyperon) produced in the interior of such system, taking into account the effect of the final-state interactions, of these particles with the surrounding pions (that is the dominant effect), as we made in [2].

Now, let us turn our attention to the final-state interactions. The most important case to be considered is the $\pi\Lambda$ ($\pi\bar{\Lambda}$), as it is the most probable interaction. The relative energy of this interaction is not so high, despite the fact that these particles are observed with high energies in the laboratory system of reference. This interaction may be described by effective chiral lagrangians, as we made in [26]-[28], where the resonance $\Sigma^*(1385)$ in the intermediate state is a key element. These lagrangians are

\[
\mathcal{L}_{\Lambda\pi\Sigma} = \frac{g_{\Lambda\pi\Sigma}}{2m_\Lambda} \left\{ \sum \gamma_\mu \gamma_5 \bar{\pi} \Lambda \right\} \partial^\mu \phi + h.c.
\]

(4)

\[
\mathcal{L}_{\Lambda\pi\Sigma^*} = g_{\Lambda\pi\Sigma^*} \left\{ \sum \gamma_\mu \left[ g_{\mu\nu} - \left( Z + \frac{1}{2} \right) \gamma_\mu \gamma_\nu \right] \bar{\pi} \Lambda \right\} \partial^\nu \phi + h.c.,
\]

(5)

where $\phi$ is the pion field and $Z$ is a parameter representing the possibility of the off-shell-resonance having spin 1/2.

The considered diagrams for the scattering amplitude are shown in Figure 3. The scattering amplitude determines the cross sections $d\sigma/d\Omega$ and $d\sigma/dt$, and the polarization. More details on the calculations may be found in [2], [27] and [26]. The $\Lambda$ polarization, as a function of $x = \cos \theta$, where $\theta$ is the scattering angle, is shown in Figure 4.

![FIG. 3: Diagrams for $\pi\Lambda$ Interaction](image)

One must observe that this model, that we proposed in 2001 [26], has made a very good prediction for the $\pi\Lambda$ phase shift at the $\Xi$ mass, $\delta_p - \delta_S = 4.3^\circ$, result that has been confirmed experimentally at the Fermilab in the HyperCP experiment in 2003 [29, 30], where they obtained $\delta_S - \delta_p = (4.6 \pm 1.4 \pm 1.2)^\circ$. This result validates our model for the $\pi\Lambda$ interaction.

With the knowledge of the velocities distribution and of the final interactions, we are able to calculate the average polarization of the produced particles in the same way we made in [2].

The average polarization may be calculated by the expression

\[
\langle \vec{P} \rangle = \frac{\int \left( \vec{P}^\mu d\sigma/dt \right) G \ d\alpha \ d\xi \ d\phi \ d\vec{p} \ d\vec{\pi}_0 \ d\vec{\pi}_0' \ d\vec{\pi}_0''} {\int \left( d\sigma/dt \right) G \ d\alpha \ d\xi \ d\phi \ d\vec{p} \ d\vec{\pi}_0 \ d\vec{\pi}_0''},
\]

(6)

where $\vec{\Lambda}_0'$ is the $\Lambda$ momentum and $\vec{\pi}_0''$ is the pion one. The factor $G$ that appears in eq. (6) contains the statistical weights of the production of the particles and the ones relative to the expansion of the fluid, and can be written as

\[
G = \frac{(dp/d^3u)}{(\exp \left( E_{\pi_0}'/T \right) - 1) (\exp \left( E_{\pi_0}'/T \right) + 1)} \Lambda_0'^2 \pi_0''^2
\]
where \( \frac{d\rho}{d^3u} \), is given by (1).

With this procedure we obtained the results shown in Figs. 3 and 4. As we can see, the resulting polarization is very small (smaller than 1%) for all values of the centrality, and are in good accord with the experimental data for both \( \Lambda \) and \( \bar{\Lambda} \).

It is known that in high energy \( p-A \) collisions, the \( p \rightarrow \Lambda \) process, produces polarized \( \Lambda \) hyperons. This result may be explained in terms of a quark exchange, of the type \( u \rightarrow s \), where an \( u \) quark of the incoming proton is exchanged by a \( s \) quark, and this reaction leads to significant polarization, transversal to the reaction plane. In \( A-A \) collisions this effect is not expected to occur. As pointed by Panagiotou in 1986, a vanishing polarization should be considered as a sign of quark-gluon plasma formation. In the polarization of such reactions is well studied, and it has been shown that a very small polarization is expected. As it was shown in, if we consider a polarized hadron, produced in the interior of a quark-gluon plasma, observing that the mean free path for these particles is considerably high (in \( A-A \) collisions), the effect of successive rescattering is to attenuate the effect of this
polarization and even the information of the initial plane of production is lost. Interesting ideas about these processes may be found in [16], [17]. So, according to the models above, in high energy collisions, the hyperons are produced unpolarized, and is expected that this polarization becomes smaller after the rescattering. But what should happen if the final-state interactions are considered?

Final-state interactions is a kind of effect that is very important in many systems, as for example, in the study of CP violation in non-leptonic hyperon decays, where the final amplitude is determined by the amplitude resulting from the final-state strong interactions [28], [31], [32]. As we have shown [2], this effect is fundamental in the understanding of the polarization of anti-hyperons in pA collisions. So, it is very reasonable to think that something similar might occur in heavy-ion collisions, where the systems are very large, and the energy, very high. In a large system, such as a RHIC collision, the probability of final interactions increase, and this effect becomes more important. The question is if a unpolarized produced Λ, may become polarized, after the final interactions.

As we verified, in p-A collisions [2], significant polarization may be obtained when unpolarized particles interact near the surface, as for example in the Ξ⁺ production. In this paper, performing the calculations, we have shown that the final polarization remains very small (almost negligible), and this fact is due to two reasons. The first one, is that the asymmetry in the polarization occurs due to the asymmetry of the system, what is determined by the parameter β, that shows the shape of the rapidity distribution. For large values of β (~2-3, that appears in p-A collisions), the forward direction this distribution is sharp, and polarization occurs. In A-A collisions, as we have shown, β is very small (β=0.14 for the data studied in this paper), so the distribution is smooth, what determines cancelation of the final polarization. The second reason, is that the Λ polarization in the πΛ interaction is not large (see Figure 4), and when the average is calculated, it is almost totally washed out. So, the mechanism that is responsible for the polarization in p-A collisions, in high energy A-A collisions has exactly the opposite effect, and destroys most of the signs of polarization. We must remark the consistency of the hydrodynamical approach for these collisions that works for p-A and for A-A collisions.

A final question is if a particle that obtains a large polarization in the final interactions (as for example Ξ or Σ, see [2]) may be observed with some polarization in the RHIC systems. This question shall be discussed in a next work.
