(Dated: February 21, 2014)

We investigate theoretically the conditions under which a multi-mode nanomechanical resonator, operated as a purely mechanical parametric oscillator, can be driven into highly nonclassical states. We find that when the device can be cooled to near its ground state, and certain mode matching conditions are satisfied, it is possible to prepare distinct resonator modes in quantum entangled states that violate Bell inequalities with homodyne quadrature measurements. We analyze the parameter regimes for such Bell inequality violations, and while experimentally challenging, we believe that the realization of such states lies within reach. This is a re-imagining of a quintessential quantum optics experiment by using phonons that represent tangible mechanical vibrations.

I. INTRODUCTION

Reaching the quantum regime with mechanical resonators has been a long-standing goal in the field of nanomechanics. In recent experiments, such devices have been successfully cooled down to near their quantum ground states, and in the future may be used for quantum metrology, as quantum transducers and couplers between hybrid quantum systems, for quantum information processing, and for exploring the limits of quantum mechanics with macroscopic objects. In many of these applications it is essential to both prepare the nanomechanical system in highly nonclassical states and to unambiguously demonstrate the quantum nature of the produced states.

Nonclassical states of harmonic resonators can be achieved by introducing time-dependent parametric modulation or via nonlinearities. The latter can be realized by a variety of techniques, for example by coupling to a superconducting qubit, coupling to additional optical cavity modes, applying external nonlinear potentials, or via intrinsic mechanical nonlinearities in the resonator itself. Using such nonlinearities, specific modes of a nanomechanical resonator could potentially be prepared in a rich variety of different nonclassical states, such as quadrature squeezed states, subpoissonian phonon distributions, Fock states, and quantum superposition states. Quantum correlations and entanglement between states of distinct oscillator modes could also be potentially generated, typically taking the form of entangled phonon states and two-mode quadrature correlations and squeezing. Experimentally, nonlinear interactions between modes of nanomechanical resonators have already been used for parametric amplification and noise squeezing. Various schemes have proposed using nonlinear dissipation processes to realize steady state entanglement. In a similar direction, a recent proposal looked at ways to couple different internal mechanical modes of a nanomechanical system via ancillary optical cavities. Also, Rips et al. looked at ways to prepare nonclassical states using enhanced intrinsic mechanical nonlinearities.

Here we consider the generation of nonclassical states and the subsequent violation of Bell inequalities by the use of similar intrinsic mechanical nonlinearities. We focus on a model relevant to a recent experimental realization of a phonon laser, where a single mechanical device exhibits significant coupling between three internal modes of deformation, due to asymmetries in the beam, and selective activation using external driving. Here we examine that same intrinsic inter-mode interaction in the quantum limit. A schematic illustration of the device considered here is shown in Fig. 1, though this is not intended to be representative of the ideal realization or measurement scheme for operating in the quantum limit. In most of our discussion we do not consider an explicit physical setup but rather focus on set-

![FIG. 1: (Color online) Schematic illustration of a conceptual nanomechanical resonator with two homodyne measurement setups that probe two different modes of oscillation. The beam can oscillate in a large number of vibrational and flexural modes with different frequencies. The two homodyne detectors measure the mode quadratures $X_1(\phi)$ and $X_2(\theta)$ with frequencies $\omega_1/2\pi$ and $\omega_2/2\pi$, respectively. By analyzing the correlations between the $X_1(\phi)$ and $X_2(\theta)$ quadratures, it is possible to determine whether or not the mode states are quantum-mechanically entangled.](image-url)
ting bounds on the fundamental system parameters necessary to realize the phenomena we discuss. The model we derive consists of an adiabatically-eliminated pump mode which drives the interaction between two lower-frequency signal and idler modes. We show that in the transient regime one can obtain violations of a Bell inequality based on correlations between quadrature measurements of the signal and idler modes. This is a re-imaging of a quintessential quantum optics experiment by using phonons that represent tangible mechanical vibrations.

This paper is organized as follows: In Sec. [II] we introduce the general model and the Hamiltonian for a nonlinear nanomechanical device. In Sec. [IIA] we consider a regime in which a parametric oscillator is realized using three modes in the mechanical system, and in Sec. [IIB] we introduce an effective two-mode model, valid when the pump mode can be adiabatically eliminated, and we analyze the types of nonclassical states that can be generated in this system. In Sec. [IIIB] we review Bell’s inequality using quadrature measurements, and in Sec. [IV] we analyze the conditions for realizing a violation of this quadrature-based Bell inequality with the mechanical system in the parametric oscillator regime studied in Sec. [IIIB]. Finally we discuss the outlook for an experimental implementation using either intrinsic nonlinearities in Sec. [V], or, as an alternative, optomechanical nonlinearities in Sec. [VA].

We summarize our results in Sec. [VII].

II. MODEL

The general Hamiltonian for a nonlinear multimode resonator, describing both the self-nonlinearities and multimode couplings up to fourth-order, can be written as:

\[ H = \sum_{k} \omega_{k} a_{k}^\dagger a_{k} + \sum_{klm} \beta_{klm} x_{k} x_{l} x_{m} + \sum_{klmn} \eta_{klmn} x_{k} x_{l} x_{m} x_{n} + O(x^{5}), \]  

where \( \omega_{k} \) is the frequency, \( a_{k} \) is the annihilation operator, and \( x_{k} = a_{k}^\dagger + a_{k} \) is the quadrature of the mechanical mode \( k \). Here the basis has been chosen so that linear two-mode coupling terms are eliminated. The third-order mode-coupling tensor \( \beta_{klm} \) describes the odd-term self-nonlinearity and the trilinear multimode interaction. The fourth-order terms describes the even-term self-nonlinearity and fourth-order multimode coupling. In symmetric systems the fourth-order terms dominate (odd terms vanish due to symmetry), and it has been proposed elsewhere that they can be used to create effective mechanical qubits. The possible combination of both third and fourth-order terms will be briefly considered in the final section. The strength of the nonlinearity depends on the fundamental frequency (length) of the resonator, and can be enhanced by a range of techniques.

In this work we focus on the three-mode coupling terms, as these are necessary to generate the states that violate continuous variable Bell inequalities. Such terms vanish in symmetric systems and thus depend on the degree of asymmetry in the mechanical device which again can be enhanced with fabrication techniques. Our approach in the following is to identify the ideal situation under which one can realize these rare Bell inequality violating states. Ultimately these states will be degraded by losses (which we investigate), but also by unwanted nonlinearities from the above Hamiltonian.

A. Parametric oscillator regime

Nanomechanical devices of the type described in the previous section have a large number of modes with different frequencies which depend on the microscopic structural properties of the beam. Here we focus on three such modes (labelled as \( k = 0, 1, 2 \)) which are chosen such that they satisfy the phase-matching condition \( \omega_{1} + \omega_{2} = \omega_{0} + \Delta_{0} \), where \( \Delta_{0} \ll \omega_{0} \). In this case we can perform a rotating-wave approximation to single out the slowly-oscillating coupling terms, and obtain the desired effective three-mode system, neglecting any higher-order non-linearities. In the original frame, the Hamiltonian with this rotating-wave approximation is

\[ H = \sum_{k=0}^{2} \omega_{k} a_{k}^\dagger a_{k} + i \kappa (a_{1} a_{2} a_{0} - a_{1} a_{2} a_{0}^\dagger), \]  

where \( a_{1} \) and \( a_{2} \) are the signal and idler modes, respectively, and \( a_{0} \) is the pump mode. Furthermore, we apply a driving force that is nearly resonant with \( \omega_{0} \), with frequency \( \omega_{0} = \omega_{0} - \Delta_{L} \), \( |\Delta_{L}| \ll \omega_{0} \), and transform the above Hamiltonian to the rotating frame where the resonant drive terms are time-independent,

\[ H = \Delta_{L} a_{0}^\dagger a_{0} + \sum_{k=1,2} \Delta_{k} a_{k}^\dagger a_{k} + i \kappa (a_{1} a_{2} a_{0} - a_{1} a_{2} a_{0}^\dagger) - i (E a_{0}^\dagger - E^* a_{0}). \]  

Here \( \Delta_{1} = \Delta_{2} = (\Delta_{0} - \Delta_{L})/2 \), \( \kappa = \beta_{012} \) is the inter-mode interaction strength, and \( E \) is the driving amplitude of
mode $a_0$. See Fig. 2A for a visual representation of the mode-matching condition and the detuning parameters $\Delta_0$ and $\Delta_L$.

This is an all-mechanical realization of the general three-mode parametric oscillator model in nonlinear optics[16] where mode $a_0$ is the quantized pump mode, and modes $a_1$ and $a_2$ are the signal and idler modes, respectively.

B. Effective two-mode model

We assume that in this purely nanomechanical realization of the parametric oscillator model, Eq. (3), all three mechanical modes interact with independent environments. We describe these processes with a standard Lindblad master equation on the form

$$\dot{\rho} = -i[H, \rho] + \sum_k \gamma_k \left\{ (N_k + 1)D[a_k] + N_kD[a_k^\dagger] \right\} \rho$$

(4)

where $D[a_k] \rho = a_k \rho a_k^\dagger - \frac{1}{2} a_k^\dagger a_k \rho - \frac{1}{2} \rho a_k^\dagger a_k$ is the dissipator of mode $a_k$, $\gamma_k$ is the corresponding dissipation rate, and the average thermal occupation number is $N_k = (\exp(\hbar \omega_k \beta) - 1)^{-1}$. Here $\beta = 1/k_B T$ is the inverse temperature $T$, and $k_B$ is Boltzmann’s constant.

Assuming that the pump mode is strongly damped compared to the signal and idler modes, $\gamma_0 \gg \gamma_1, \gamma_2$, and that the pump-mode dissipation dominates over the coherent interaction, $\gamma_0 \ll \langle H \rangle \sim \kappa(a_1^\dagger a_2^\dagger a_1 a_2)$, one can adiabatically eliminate the pump mode from the master equation given above. Here we also assume that the high-frequency pump mode is at zero temperature, $N_0 = 0$, while the temperatures of modes $a_1$ and $a_2$ can remain finite. This results in a two-mode master equation that includes correlated two-phonon dissipation, where one phonon from each mode dissipates to the environment through the pump mode, in addition to the original single-phonon losses in each mode:

$$\dot{\rho} = -i[H', \rho] + \gamma D[a_1 a_2] \rho + \sum_{k=1,2} \gamma_k \left\{ (N_k + 1)D[a_k] + N_kD[a_k^\dagger] \right\} \rho,$$

(5)

where the effective two-phonon dissipation rate is

$$\gamma = \frac{\kappa^2 \gamma_0}{|\gamma_0/2 + i\Delta_L|^2}. \quad (6)$$

The reduced two-mode Hamiltonian is given by

$$H' = \sum_{k=1,2} \Delta_k a_k^\dagger a_k + i(\mu a_1^\dagger a_1^\dagger a_2^\dagger a_2^\dagger - \mu^* a_1 a_2) + \chi a_1^\dagger a_1 a_2^\dagger a_2$$

(7)

with the two-mode interaction strength

$$\mu = \frac{E \kappa}{\gamma_0/2 + i\Delta_L}, \quad (8)$$

and the effective cross-Kerr interaction strength

$$\chi = -\frac{\kappa^2 \Delta_L}{|\gamma_0/2 + i\Delta_L|^2}, \quad (9)$$

which vanishes when the driving field is at exact resonance with the pump mode. In the following we will generally assume that this resonance condition can be reached, and $\Delta_L$ will be set to zero in the equations above.

In this resonant limit the Hamiltonian $H'$ describes an ideal two-mode parametric amplifier, which is well-known to be the generator of two-mode squeezed states[19]. When applied to the vacuum state, or a low-temperature thermal state, the resulting two-modes squeezed states are nonclassically correlated[20], but when viewed individually, both modes appear to be in thermal states. In
In the highly idealized case when single phonon dissipation in the $a_1$ and $a_2$ modes is absent, i.e., $\gamma_1 = \gamma_2 = 0$, but with $\gamma_0 > 0$, the model Eq. (5) produces a steady state of the form

$$\rho = \frac{1}{I_0(2r^2)} \sum_{m,n} r^{2m+2n} m! n! |m,m\rangle \langle n,n|,$$

(10)

where $I_0$ is the zeroth order modified Bessel function and $r = \sqrt{2E/\kappa}$. The special structure of this steady state, with equal number of phonons in each mode, is because both the Hamiltonian and two-phonon dissipator conserve the phonon-number difference $a_0^\dagger a_2 - a_1^\dagger a_1$. However, this symmetry is broken if the single-phonon dissipation processes are included in the model, i.e. $\gamma_1, \gamma_2 > 0$. The state Eq. (11) is visualized in Fig. 3 for the specific set of parameters given in the figure caption. Figure 3(a-b) show the Fock-state distribution and the Wigner function for the modes $a_1$ and $a_2$ (because of symmetry the states of both modes are identical in this case, and only one is shown). In this case the states of the two modes no longer appear to be thermal when viewed individually, but the reduced single-mode Wigner functions are positive and thus, on their own, each mode appears classical. However, together, the two-mode Wigner function can be negative. For example, there is a strong cross-quadrature correlation, as shown in Fig. 3(c). The variances of the cross-quadrature differences, in the transient approach to the steady state, are shown in Fig. 4 and exactly in the steady state the variance of the squeezed two-mode operator difference is

$$\text{Var}(x_1 - x_2) = 1 + 2r^2 \frac{I_1(2r^2)}{I_0(2r^2)} - 2r^2,$$

(11)

which in the limit of large $r$ approaches $1/2$, but has a local minimum of about 0.4 at $r \approx 0.92$. We note that for the vacuum state $\text{Var}(x_1 - x_2) = 1$, and thus this quadrature difference variance is therefore squeezed below the vacuum level for any $r > 0$. The logarithmic negativity shown in Fig. 3(d) further demonstrates the nonclassical nature of this state.

These intermode quadrature correlations, with squeezing below the vacuum level of fluctuations, are nonclassical and it has been shown that this particular state can violate Bell inequalities based on quadrature measurement, as we will discuss in the next section. In fact, this steady state is, for a certain value of $r$, a good approximation to the ideal two-mode quantum state for these kind of Bell inequalities. However, it has also been shown that in the presence of single phonon dissipation the steady state two-mode Wigner function is always positive, and thus exhibits a hidden-variables description and cannot violate any Bell inequalities. Fortunately, this is only the case for the steady state, and there can be a significant transient period in which the two-mode system is in a state that can give a violation.

In the following we consider two regimes; the steady state, and the slow transient dynamics of a system that is originally in the ground state, and approaches the new steady state after the driving field has been turned on.

### III. BELL INEQUALITIES FOR NANOMECHANICAL SYSTEMS

Verifying that a nanomechanical system is in the quantum regime, and that the states produced in the system are nonclassical, can be sometimes be experimen-
tally challenging, largely because of the difficulty in im-
plementing single-phonon detectors in nanomechancial 
systems. As has been done in circuit QED\cite{13,14}, measur-
ing a nonlinear energy spectrum\cite{15} would be a convincing 
indication that the system is operating in the quantum 
regime, although it does not imply that the state of the 
system is nonclassical, and all quantum nanomechanical 
systems need not necessarily be nonlinear. A number of 
techniques could be used to demonstrate that the state 
is nonclassical\cite{25,26}, for example reconstructing the Wigner 
function using state tomography and looking for negative 
values, or evaluating entanglement measures such as the 
logarithmic negativity (for Gaussian states) or entangle-
ment entropy (suitable only at zero temperature).

Here we are interested in a nonclassicality test that 
can be evaluated using joint two-mode quadrature mea-
surements. The two-mode squeezing shown in the pre-
vious section can be considered as an entanglement 
 witness\cite{25,26}, and was recently investigated experimen-
tially in an opto-mechanical device\cite{27,28}. The quadrature-
based Bell inequality can be seen as another, stricter,
example of a nonclassicality test, and in the following we 
focus on the possibility of violating these Bell inequalities 
with the nanomechanical system outlined in the previous 
section. Even though one cannot rule out the locality-
loophole in such a system, and thus a violation would 
lack any meaning as a strict test of Bell nonlocality\cite{29}, it 
would still serve as a very satisfying test for two-mode 
entanglement.

The original Bell inequalities are formulated for di-
ichotomic measurements, with two possible outcomes. 
However, dichotomic measurements are not normally 
available in harmonic systems like the nanomechanical 
systems considered here, where the measurement out-
comes are, for the most part, continuous and unbound. 
In this continuous-variable limit one must choose how 
to perform a Bell inequality test with care. General-
ized inequalities for unbound measurements exist\cite{30}, 
but are both extremely challenging to implement and hard 
to violate. Fortunately one can implement CHSH-type 
Bell inequality by binning quadrature measurements, 
and thus obtaining a dichotomic bound observable. Munro\cite{30} 
showed that, while in general it is hard to generate states 
which can violate such an inequality, it is possible to gen-
erate precisely the type of states which do cause a vi-
olation with a nondegenerate parametric oscillator, which 
is analogous to the system we investigate here.

One possible binning strategy\cite{24,31} for the continuous 
outcomes of quadrature measurements of the mechanical 
modes is to classify the outcomes as 1 if the measurement 
outcome is \(X_\theta > 0\), and 0 otherwise. The probability 
of the outcomes 0 and 1 for the two modes can then be 
written

\[
P_{\alpha,\beta}(\theta, \phi) = \int_{L(\alpha)}^{U(\alpha)} \int_{L(\beta)}^{U(\beta)} d^2X p(X_1^\theta, X_2^\phi) |\rho| \]  

(12)

where

\[
L(\alpha) = \begin{cases} 
0 & \text{if } \alpha = 1 \\
-\infty & \text{if } \alpha = 0 \
\end{cases}, 
U(\alpha) = \begin{cases} 
\infty & \text{if } \alpha = 1 \\
0 & \text{if } \alpha = 0 
\end{cases} \]  

(13)

Here \(\rho\) is the two-mode density matrix and \(p(X_1^\theta, X_2^\phi) |\rho|\) 
is the probability distribution for obtaining the measurement 
outcomes \(X_1^\theta\) and \(X_2^\phi\) for the signal and idler mode 
quadratures

\[
x_1^\theta = a_1 e^{-i\theta} + a_1^\dagger e^{i\theta}, \quad x_2^\phi = a_2 e^{-i\phi} + a_2^\dagger e^{i\phi} \]  

(14)\hspace{1cm}(15)

respectively. This probability distribution is given by

\[
p(X_1^\theta, X_2^\phi) |\rho| = \langle X_1^\theta, X_2^\phi | \rho | X_1^\theta, X_2^\phi \rangle = \sum_{m,n,p,q} \rho(m,n),(p,q) e^{-i(m\theta+n\phi) + i(p\theta+q\phi)} \times e^{-X_1^\theta X_1^\theta^\dagger} H_m(X_1) H_n(X_2) H_p(X_1) H_q(X_2) \]  

(16)

where \(H_n(x)\) is the Hermite polynomial of \(n\)th order, and 
where we have written the density matrix in the two-
mode Fock basis,

\[
\rho = \sum_{m,n,p,q} \rho(m,n),(p,q) |m,n\rangle \langle p,q| \]  

(17)

The integral in Eq. (12) can be evaluated analytically\cite{10}, 
but in general the sum in Eq. (16) cannot.

Treating the binned quadrature measurements as di-
ichotomic observables we can write the standard Bell’s 
inequalities in the Clauser-Horne (CH) form

\[
B_{CH} = \frac{P_{11}(\theta, \phi) - P_{11}(\theta', \phi) + P_{11}(\theta', \phi') - P_{11}(\theta, \phi')}{P_1(\theta') + P_1(\phi)} \]  

(18)

which for a classical state satisfies \(|B_{CH}| \leq 1\), and in the 
Clauser-Horne-Shimony-Holt (CHSH) form

\[
B_{CHSH} = E(\theta, \phi) - E(\theta', \phi) + E(\theta, \phi') + E(\theta', \phi') \]  

\[
E(\theta, \phi) = P_{11}(\theta, \phi) + P_{00}(\theta, \phi) 
- P_{10}(\theta, \phi) - P_{01}(\theta, \phi), \]  

(19)\hspace{1cm}(20)

which for a classical state satisfies \(|B_{CHSH}| \leq 2\). Here we have also used

\[
P_1(\theta) = \int_0^{\infty} \int_{-\infty}^{\infty} d^2X p(X_1^\theta, X_2^\phi) |\rho|. \]  

(21)

Both \(B_{CH}\) and \(B_{CHSH}\) are in general functions of the four 
angles \(\theta, \phi, \theta',\) and \(\phi'.\) However, to reduce the num-
ber of parameters here we consider the angle parameter-
ization \(\theta = -2\phi, \phi = 3\phi, \theta' = 0,\) and \(\phi' = \phi,\) which only 
leaves a single free angle parameter \(\phi.\) In principle this 
can reduce the magnitude of violation one can observe, 
but as we will see this parameterization still allows viola-
tions to occur for the types of states we are interested in 
here. In the following we evaluate both \(B_{CH}\) and \(B_{CHSH}\) 
using this angle parameterization.
IV. VIOLATION OF BELL’S INEQUALITY WITH NANOMECHANICAL RESONATORS

In this section we investigate the conditions under which the states formed in the multimode nanomechanical system may violate Bell’s inequality. We emphasize again that in this context we are interested in Bell’s inequality as a test that can demonstrate entanglement between different mechanical modes. We begin with an analysis of the steadystate for the idealized model with $\gamma_1, \gamma_2 = 0$, and then turn our attention to the transient behaviour for finite $\gamma_1$ and $\gamma_2$.

A. Steady state

With $\gamma_1, \gamma_2 = 0$, the steady state is given by Eq. (10), and inserting this state in the Bell inequalities Eqs. [18] gives an expression as a function of the steady state parameter $r$ and the angle $\varphi$ that can be optimized for maximum Bell violation. The optimal value of the angle turns out to be $\varphi = \pi/4$, and the resulting equation for optimal $r$ is

$$I_0 (2r^2) \frac{dG(r)}{dr} = 4r^2 I_1 (2r^2) G(r),$$  \hspace{1cm} (22)

but the sum over Fock-state basis that comes from Eq. (10) cannot to our knowledge be evaluated in a simple analytical form, so we have

$$G(r) = \sum_n \sum_{m > n} \frac{8 (2r^2)^{n+m} \pi}{(n!m!)^2 (n-m)^2} [F(n,m) - F(m,n)]^2 \times \{3 \cos [(n-m) \varphi] - \cos [3 \varphi (n-m)]\},$$  \hspace{1cm} (23)

and

$$F(n,m) = \left[ \Gamma \left( \frac{1}{2} - \frac{n}{2} \right) \Gamma \left( - \frac{m}{2} \right) \right]^{-1},$$  \hspace{1cm} (24)

as given in Ref. [46] Solving Eq. (22) numerically gives $r_{opt} \approx 1.12$, as reported in Ref. [51]. The corresponding steady state Eq. (10) for $r_{opt}$ is visualized in Fig. 3. We note that for this optimal Bell violating state the mean phonon number in each mode is only $\langle n \rangle \approx 0.94$, which highlights the need to operate the system near its ground state. If fact, when $\langle n \rangle > 1$ no Bell inequality violation can be observed.

In our nanomechanical model this translates to an optimal driving strength, $E_{opt} = r_{opt}^2 \kappa/2$, that maximizes the Bell inequality violation for a given nonlinearity $\kappa$. This optimal driving amplitude $E_{opt}$ applies to the steady state of the idealized model without single-phonon dissipation. With finite single-phonon dissipation, the steady state does not violate any of the Bell inequalities. However, as we will see in the following section, $E_{opt}$ still gives a good approximation for the optimal transient violation. While these transients are harder to capture, recent experiments on opto-mechanical systems have shown they are in principle possible and relevant for the alternative proposal in the final section below. How far one can go with using multiple ancilla optical or microwave cavities to perform similar measurements on different internal modes of a single mechanical device is not yet clear.
FIG. 6: (Color online) Violation of the normalized quadrature CHSH Bell inequality (redish region) as a function of time $t$ and the inter-mode coupling $\kappa$ (a,d), the pump mode driving amplitude $E$ (b,e), and the pump-mode dissipation rate $\gamma_0$ (c,f). The ideal case without signal and idler mode dissipation is shown in (a-c), and (d-e) include signal and idler mode dissipation with equal dissipation rates $\gamma_1 = \gamma_2 = 0.001$. In (a-c) there is a parameter window for $\kappa$ and $E$ which results in a violation for sufficiently large $t$, as well as in the steady state. However, in (d-e) there is no violation in the steady state, but during a transient time a violation may still occur for suitably chosen parameters. Apart from the parameters on the vertical axes, the parameters were kept fixed at the same values as given in Fig. 3, and denoted by a bar over the symbol in the axes.

B. Transient

Since the more realistic model, with finite single-phonon dissipation processes, does not produce a steady state that violates any of the Bell inequalities, we are lead to investigate transient dynamics. Here we focus on the transient which occurs when the driving field $E$ is turned on after the relevant modes have been cooled to their ground states. The state of the system then evolves from the ground state to the steady state that does not violate the Bell inequalities. However, if the single phonon dissipation processes are sufficiently slow there can be a significant time interval during which the state of the system does violate the Bell inequalities.

To investigate this transient dynamics we numerically evolve the effective two-mode system described by the master equation, Eq. (5), and evaluate the $B_{\text{CH}}$ and $B_{\text{CHSH}}$ quantities as a function of time and the angle $\varphi$. The results shown in Fig. 5 for the situations with and without signal and idler mode dissipation and at zero temperature, demonstrate that the nanomechanical system we consider can indeed be driven into a transient state that violates both types of Bell inequalities. With losses the onset of violation is proportional to $\gamma_0/\kappa^2$, and the time at which the violation cease is proportional to $\gamma_1^{-1}, \gamma_2^{-1}$, so if

$$\gamma_1, \gamma_2 \ll \kappa^2/\gamma_0,$$  

(25)

we expect a significant period of time during the transient where the inequalities will be violated. We note that in Fig. 5(a), the regions of violation for the CH and CHSH inequalities are identical, and this is, according to our observations, always the case for this model and angle parametrization. Because of this, in the following we only show the results for the CHSH inequality.

To further explore the parameter space that can produce a Bell-inequality violation we evolve the master equation as a function of time and the parameters $E$, $\kappa$ and $\gamma_0$, for both the ideal case with dissipation-less signal and idler modes, $\gamma_1 = \gamma_2 = 0$, and for the case including signal and idler mode dissipation, $\gamma_1, \gamma_2 > 0$. In these simulations the initial state is always the ground state, and we take the temperature of the signal and idler modes to be zero. The results are shown in Fig. 6(a-c) and (e-f), respectively. From Fig. 6 it is clear that for the case $\gamma_1 = \gamma_2 = 0$, there exist optimal values of $\kappa$ and $E$, given that other parameters are fixed, that produce steady states that maximally violates the Bell inequality (marked with dashed lines in the figures). However, importantly, we also note that the optimal values for $\kappa$ and $E$ for the steady state of the ideal model also give a good indicator for the optimal regime for the Bell violation in the transient of the case with finite single-phonon dissipation, when additionally taking into account the time scales for the transient given in Eq. (25).

When the signal and idler modes have finite temper-
The thermal occupation number of even 0 must be very small: An average transient Bell inequality violation, the average thermal phonons are two-fold: It reduces the transient time-interval during which a violation can be observed, reduced, as shown in Fig. 7. The detrimental effects of transient time-interval during which a violation can be observed, and the nonlinear interaction strength required to be able to see any violation at all increases. In fact, to observe a transient Bell inequality violation, the average thermal occupation number must be very small: An average thermal occupation number of even 0 phonon in the signal and idler mode is sufficient to inhibit any Bell violation with the system we have considered here. Excellent ground-state cooling of both modes is a prerequisite to obtaining a violation.

**V. EXPERIMENTAL OUTLOOK**

As can be seen in Fig. 6 and Fig. 7, the violation of a Bell inequality in the system we consider here requires, as expected, a combination of low temperature, large nonlinearity, and transient quadrature measurements. These conditions can all be rather challenging to satisfy in an experimental system, but on the other hand they are exactly the type of conditions that one can expect would have to be satisfied for realistic quantum mechanical applications in these devices. The Bell inequality violation can therefore be seen as a benchmark that indicates that entangled quantum states can be generated and detected with high precision.

While one can imagine cryogenics and side-band cooling techniques can satisfy the first criteria, the ultimate upper limit of the strength of intrinsic nonlinearities in mechanical systems is not clear. In a recent experiment extremely large nonlinear intra-mode coupling was observed in a carbon nanotube system when the modes had frequencies which were integer multiples of each other. In that case a strong effective mode-mode coupling was also found, which is required for generating the Bell inequality violating states we consider here. Nonlinear mode coupling has also been demonstrated and analyzed in doubly-clamped beam resonators, and circular graphene membrane resonators. Also, recent studies have proposed enhancing the nonlinearity per phonon by reducing the fundamental frequency of the mechanical oscillator, which essentially amounts to increasing the ground state displacement. Thus, there is progress in realizing nonlinear mode interaction in several types of nanomechanical systems, and sufficiently strong nonlinearities to produce Bell inequality violating states should be obtainable in these devices, although further progress in this experimental work in this direction may be required.

Performing transient quadrature measurements of selected modes of the mechanical resonator is another experimental challenge. However, the displacement of a nanomechanical resonator can be converted to electrical signals and measured for example using a range of different techniques, for example piezoelectric schemes, or by capacitive coupling to a microwave circuit. In recent experiments, transient quadrature measurements of a nanomechanical system were carried out with high precision and level of control. Aslo, in microwave electronics, quadrature measurements in the quantum regime have been applied to measure two-mode squeezing, state tomography, and entanglement. Given a sufficiently efficient transducer from mechanical displacement to electrical signals, the outlook for the required measurements for evaluating the quadrature Bell inequality is therefore encouraging.

**A. Optomechanical realization**

As an alternative to the purely mechanical scheme discussed so far one could observe the similar quadrature-based Bell inequality violations in an optomechanical setup akin to that proposed in Refs. and where a single mechanical mode is coupled to two optical cavities, e.g., in a membrane-in-the-middle geometry or within a photonic crystal cavity. The most straightforward implementation would be to use the mechanical mode as the pump mode which then acts to entangle the optical modes. The optical modes are coupled due to a photon tunneling, and the resulting hybridized modes replace the mechanical signal and idler modes and discussed in this work. On resonance this again leads to the same interaction we use in Eq. 2. The main motivation of
inducing this interaction in these earlier works was to engineer anharmonic energy levels. This anharmonicity allows specific transitions to be addressed with external laser fields allowing one to use such devices as single-phonon/photons and for non-demolition measurements of phonons or photons. In the limit where the mechanical pump mode can be driven and adiabatically eliminated, one in principle observe Bell inequality violations in the (hybridized) quadrature measurements of the two optical cavities.

VI. COMBINING EVEN AND ODD NONLINEARITIES: COUPLING MECHANICAL QUBITS

In the previous calculations we have been exclusively considering the effect of odd nonlinearities which can only arise in asymmetric mechanical systems. In purely symmetric devices the even order terms dominate, arguably the most important of which is the $x^4$ Duffing nonlinearity. Recent works have examined how this induces an anharmonic energy spectrum in the fundamental mode of a nanomechanical system, and outlined how this anharmonic spectrum can be used as an effective qubit for quantum computation. Naturally one can consider the effect of both the third order coupling we have outlined here, and the third and fourth order Duffing self-anharmonicity. Ultimately the relative strengths of these different terms depend strongly on the overlap between the different mode shapes within the device, the geometry of the device, and the effect of various nonlinearity enhancing mechanisms. A naive investigation of the contributions from these quartic terms suggest they only work to degrade the Bell inequality violation we discuss here. However, going beyond the regime we have outlined thus far, one may note that, by changing the frequency of the driving field in Eq. (1) one can get an excitation-preserving beam-splitter type of interaction between the signal and idler modes.

$$H_{\text{int}} = \mu(a_1^\dagger a_2 + a_2^\dagger a_1). \quad (26)$$

If this is combined with a sufficiently strong third or fourth-order self nonlinearity, such that the lowest lying energy states of each mode can be considered as a two-level system, one has a means to couple different mechanical qubits in a single device. It may be possible to construct similar interactions with ancilla cavities and optomechanical interaction\textsuperscript{4}.\textsuperscript{6} The original parametric interaction described in Eq. (8) is not useful for this purpose as it takes one out of a single excitation subspace, as does the two-phonon dissipation.

VII. CONCLUSIONS

We have investigated a regime of a multimode nanomechanical resonator, with intrinsic nonlinear mode coupling, in which three selected modes realize a parametric oscillator. In the regime where the pump mode of the parametric oscillator can be adiabatically eliminated, we have investigated the generation of entangled states between two distinct modes of oscillation in the nanomechanical resonator, and the possibility of detecting this entanglement using quadrature-based Bell inequality tests. Our results demonstrate that while realistically it will not be possible to violate any Bell inequality in the steady state, there can be a significant duration of time in which the transient evolution from the ground state (prepared by cooling) to the steady state where the state of the system violates Bell inequalities. However, to achieve this transient violation requires a relatively large nonlinear mode coupling, excellent ground state cooling, and fast and efficient quadrature measurements. These are, of course, very challenging experimental requirements, but we believe that if a quadrature Bell inequality violation is realized experimentally it would be a very strong demonstration of quantum entanglement in a macroscopic mechanical system.
