ABSTRACT

In recent years, accurate observational constraints have become available for an increasing number of Galactic X-ray binaries (XRBs). Together with proper-motion measurements, we could reconstruct the full evolutionary history of XRBs back to the time of compact object formation. In this paper, we present the first study of the persistent X-ray source Cygnus X-1 that takes into account all available observational constraints. Our analysis accounts for three evolutionary phases: orbital evolution and motion through the Galactic potential after the formation of a black hole (BH), and binary orbital dynamics at the time of core collapse. We find that the mass of the BH immediate progenitor is \(15.0\pm20.0\,M_\odot\), and at the time of core collapse, the BH has potentially received a small kick velocity of \(\lesssim 77\,\text{km\,s}^{-1}\) at 95% confidence. If the BH progenitor mass is less than \(\sim 17\,M_\odot\), a non-zero natal kick velocity is required to explain the currently observed properties of Cygnus X-1. Since the BH has only accreted mass from its companion’s stellar wind, the negligible amount of accreted mass does not explain the observationally inferred BH spin of \(a_*=0.95\), and the origin of this extreme BH spin must be connected to the BH formation itself. Right after the BH formation, we find that the BH companion is a 19.8–22.6 \(M_\odot\) main-sequence star, orbiting the BH at a period of 4.7–5.2 days. Furthermore, recent observations show that the BH companion is currently super-synchronized. This super-synchronism indicates that the strength of tides exerted on the BH companion should be weaker by a factor of at least two compared to the usually adopted strength.

Key words: binaries: close – X-rays: binaries – X-rays: individual (Cygnus X-1)

Online-only material: color figures

1. INTRODUCTION

In recent years, the number of observed black hole (BH) X-ray binaries (XRBs) has grown significantly. For these binaries, there exists a wealth of observational information about their current physical state: BH and donor masses, orbital period, donor’s position on the H-R diagram and surface chemical composition, transient or persistent X-ray emission, and Roche lobe overflow (RLO) or wind-driven character of the mass transfer (MT) process. Furthermore, proper motions have been measured at the BH and donor’s position on the H-R diagram and surface chemical composition, transient or persistent X-ray emission, and Roche lobe overflow (RLO) or wind-driven character of the mass transfer (MT) process. Furthermore, proper motions have been measured at the time of core collapse. We find that the mass of the BH immediate progenitor is \(15.0\pm20.0\,M_\odot\), and at the time of core collapse, the BH has potentially received a small kick velocity of \(\lesssim 77\,\text{km\,s}^{-1}\) at 95% confidence. If the BH progenitor mass is less than \(\sim 17\,M_\odot\), a non-zero natal kick velocity is required to explain the currently observed properties of Cygnus X-1. Since the BH has only accreted mass from its companion’s stellar wind, the negligible amount of accreted mass does not explain the observationally inferred BH spin of \(a_*=0.95\), and the origin of this extreme BH spin must be connected to the BH formation itself. Right after the BH formation, we find that the BH companion is a 19.8–22.6 \(M_\odot\) main-sequence star, orbiting the BH at a period of 4.7–5.2 days. Furthermore, recent observations show that the BH companion is currently super-synchronized. This super-synchronism indicates that the strength of tides exerted on the BH companion should be weaker by a factor of at least two compared to the usually adopted strength.

2. OBSERVATIONAL CONSTRAINTS FOR CYGNUS X-1

Cygnus X-1 was first detected in Aerobee surveys in 1964 by Bowyer et al. (1965). Soon after the discovery, it was identified as an XRB, which consisted of a compact object and a visible star HDE 226868 (Murdin & Webster 1971; Webster & Murdin 1972; Bolton 1972a). Spectroscopic observations led Walborn (1973) to classify HDE 226868 as an O9.7 Ia supergiant. Bregman et al. (1973) estimated the distance to be 2.5 kpc and set a lower limit of 1 kpc, based on the colors of field stars in the vicinity of the supergiant. Using a combination of data from David Dunlap Observatory and the Royal Greenwich Observatory, Bolton (1972b) derived the orbital period, eccentricity, and systemic radial velocity \(V_0\) to be 5.5995 \pm 0.0009 days, 0.09 \pm 0.02, and −6.0 \pm 0.1 km s\(^{-1}\), respectively. Based on the absence of X-ray and optical eclipses, the author gave a lower limit of 7.4 \(M_\odot\) on the mass of the compact object. This implied that the compact object was too massive to be a white dwarf or a neutron star. Thus, the author confirmed Webster & Murdin’s (1972) finding that the compact object is a very strong BH candidate.
Using the orbital period obtained from spectrometry and a range in the assumed degree of Roche filling of the supergiant, Gies & Bolton (1982, 1986a) found a lower mass limit of 7 M⊙ for the compact object. This confirmed that the compact object observed in Cygnus X-1 was a BH. The same authors also refined the orbital period and eccentricity to be 5.59974 ± 0.00008 and 0.021 ± 0.013, respectively, and measured V0 to be −2.0 ± 0.7 km s⁻¹. Ninkov et al. (1987) used the relationship between the equivalent width of the Hγ spectral line and the absolute magnitude of early-type supergiants to estimate the distance as 2.5 ± 0.3 kpc.

Herrero et al. (1995) performed a detailed spectroscopic analysis on the supergiant, and derived the masses to be 10.1 M⊙ and 17.8 M⊙ for the BH (M_{BH}) and the supergiant (M_{2}), respectively, if an orbital inclination angle of 35° was assumed. Using the Isaac Newton telescope, LaSala et al. (1998) measured the orbital period as 5.599 ± 0.001 days and V0 as −5.4 ± 0.1 km s⁻¹. With all the accumulated radial velocity measurements and their own spectroscopy of the supergiant, Brockopp et al. (1999) refined the orbital period to 5.59892 ± 0.000024. The proper motion of Cygnus X-1 was observed with the Very Large Base Interferometer (VLBI) between 1988 and 2001 (Lestrade et al. 1999; Stirling et al. 2001; Mirabel & Rodrigues 2003). During this period, the system’s position shifted at a rate of −4.2 ± 0.2 mas yr⁻¹ in right ascension (R.A.) and −7.6 ± 0.2 mas yr⁻¹ in declination (decl.). Meanwhile, a trigonometric parallax of 0.73 ± 0.30 mas was also measured with VLBI, which gave a distance of 1.4+0.9−0.4 kpc (Lestrade et al. 1999).

By studying the spectra obtained with the 0.9 m coude telescope of Kitt Peak National Observatory, the 2.1 m telescope of University of Texas McDonald Observatory, and the 1.9 m telescope of University of Toronto David Dunlap Observatory between 1998 and 2002, Gies et al. (2003) derived V0 as −7.0 ± 0.5 km s⁻¹ and estimated M_{BH}/M_{2} ≈ 0.36 ± 0.05. Caballero-Nieves et al. (2009) examined the supergiant’s ultraviolet spectra from the Hubble Space Telescope. Their results gave masses of 23.8 ± 6 and 11.5 ± 3 M⊙ for the supergiant and the BH, respectively. On the other hand, Shaposhnikov & Titarchuk (2007) used the X-ray quasi-periodic oscillation and spectral index relationship and deduced M_{BH} to be 8.7 ± 0.8 M⊙, which overlapped with the lower end of the M_{BH} range derived by Caballero-Nieves et al. (2009).

Recently, Reid et al. (2011) measured the trigonometric parallax of Cygnus X-1 with the National Radio Astronomy Observatory’s Very Long Baseline Array and found a distance of 1.86±0.03 kpc. The authors also reported proper-motion measurements of Cygnus X-1, which were −3.78 ± 0.06 mas yr⁻¹ in R.A. and −6.40 ± 0.12 mas yr⁻¹ in decl. Meanwhile, Xiang et al. (2011) studied the X-ray dust scattering halo of Cygnus X-1 and determined the distance to be 1.81 ± 0.09 kpc, after considering the compatibility with the parallax result. Building on the trigonometric parallax distance measurement of Reid et al. (2011), Orosz et al. (2011) performed optical data modeling of Cygnus X-1 and found the mass of the supergiant to be 19.2 ± 1.9 M⊙ and the BH to be 14.8 ± 1.0 M⊙. Using the results of Reid et al. (2011) and Orosz et al. (2011), Gou et al. (2011) determined that Cygnus X-1 hosts a near-extreme Kerr BH, with a spin parameter a_∗ > 0.95.

Unlike most of the XRBs known to host a BH, Cygnus X-1 is a persistent X-ray source. Since the supergiant is currently not overfilling its Roche lobe (Gies & Bolton 1986a), the observed X-rays are mainly powered by the accretion of stellar wind. The X-ray luminosity of Cygnus X-1 varies between two discrete levels, namely, the “hard (low) state” and the “soft (high) state.” As the system spends most of its time (~90%), see Cadolle Bel et al. (2006) in the hard state, we focus on the hard state X-ray luminosity (L_X). Frontera et al. (2001) observed Cygnus X-1 with the Narrow Field Instruments of the BeppoSAX satellite at different epochs in 1996. The authors obtained the L_X (0.5–200 keV) and the extrapolated bolometric luminosity (L_{bol}) as 2.0 × 10^{37} and 2.4 × 10^{37} erg s⁻¹, respectively, assuming a distance of 2 kpc. Using observational data obtained by the Compton Gamma Ray Observatory between 1991 and 2000, McConnell et al. (2002) derived L_{bol} to be (1.62–1.70) × 10^{37} erg s⁻¹, with the distance to the source fixed at 2 kpc. Cadolle Bel et al. (2006) observed Cygnus X-1 with the International Gamma-Ray Astrophysics Laboratory between 2002 and 2004 and measured L_X (20–100 keV) as 6.5 × 10^{36} erg s⁻¹, assuming a distance of 2.4 kpc. The authors also gave L_{bol} as 2.2 × 10^{37} erg s⁻¹.

For the systemic parameters relevant to our analysis, we adopt the most recent observational constraints, with the exception of L_{bol}. We consider all the L_{bol} values mentioned above, assuming they represent the typical X-ray variability range for this system. After rescaling their values to the parallax distance measurement by Reid et al. (2011) and considering the uncertainty in that distance, we adopt L_{bol} to be (1.17–2.35) × 10^{37} erg s⁻¹. For ease of reference, our adopted observational constraints are summarized in Table 1.

3. OUTLINE OF ANALYSIS METHODOLOGY

In our analysis, we assume that Cygnus X-1 formed in the Galactic disk, from the evolution of an isolated primordial binary at solar metallicity. In fact, Mirabel & Rodrigues (2003) suggest that Cygnus X-1 belongs to Cygnus OB3 (Cyg OB3), which is an OB association located close to the Galactic plane. We also assume that no MT via RLO occurred in the evolutionary history of this binary.

According to our current understanding, in order to form a ∼15 M⊙ stellar BH at solar metallicity, the BH progenitor in the primordial binary needs to be more massive than 120 M⊙ (Belczynski et al. 2010). Such a massive star loses its hydrogen rich envelope via stellar wind and exposes its naked helium core. At the end of nuclear evolution, it collapses into a BH. During the core-collapse event, the orbit is altered by the asymmetric mass loss from the system and a possible recoil kick imparted to the BH. If the binary survives through the core-collapse event, angular momentum loss via gravitational radiation and tidal effects causes the orbit to shrink, although wind mass loss leads to orbital expansion. In the meantime, the more evolved BH companion is losing mass via its own stellar wind at a higher rate. The system becomes a BH XRB when the BH captures a non-negligible amount of mass from its companion’s stellar wind.

In this paper, we restrict ourselves to the formation of BH XRBs through the above evolutionary channel. Like the first two papers, our goal is to track the evolutionary history of Cygnus X-1 back to the time just prior to the core-collapse event. Our analysis incorporates a number of calculations which can be summarized in four steps.

First, we identify the current evolutionary stage of the BH companion, so that all the observational constraints are satisfied. Under the assumption that the BH companion mass has not been altered by MT in the past, we model it as an isolated star. Using a stellar evolution code, we calculate a grid of evolutionary
sequences of isolated stars at different zero-age main-sequence (ZAMS) masses. We examine each sequence to find whether there exists a point in time that the calculated stellar properties, i.e., mass, radius, luminosity, and effective temperature, are all simultaneously in agreement with the currently observed properties of the BH companion. If such a period of time exists, we classify that sequence as “successful.” The current age of the BH companion can be estimated from these successful sequences, and the time expired since the BH formation can then be derived by subtracting the approximate lifetime of the BH progenitor.

Next, we consider the kinematic evolutionary history of the XRB in the Galactic potential. Starting from the current location, we follow the methodology of Gualandris et al. (2005) and use the observed three-dimensional velocity to trace the Galactic motion of Cygnus X-1 backward in time. Together with the constraints on the current age of the system derived in the first step, this allows us to determine the location and velocity of the binary at the time of BH formation (we denote these as “birth” location and velocity). By subtracting the local Galactic rotational velocity at the “birth” location from the system’s center-of-mass velocity, we derive constraints on the peculiar velocity of the binary right after the formation of the BH.

In the third step, we analyze the orbital dynamics of the core-collapse event due to mass loss and possible natal kicks imparted to the BH. In this paper, we refer to the intransits right before and after the formation of the BH by the terms “pre-SN” and “post-SN,” respectively. We start with the constrained parameter space of \( (M_{\text{BH}} \text{ and } M_2) \) derived in the first step and perform a Monte Carlo simulation scanning over the parameter space of the pre-SN binary properties. This parameter space is limited by requirements of orbital angular momentum and energy conservations, and by the post-SN binary peculiar velocity constraint derived in the second step. This calculation yields a population of simulated post-SN binaries for each successful sequence.

Finally, we follow the orbital evolution of these simulated binaries to the current epoch. Our calculation accounts for tides, wind mass loss, wind accretion onto the BH, and orbital angular momentum loss via gravitational radiation. At the end of the calculations, we require agreement between the observed and calculated orbital period and eccentricity.

4. MODELING THE BH COMPANION

Under the assumption that the companion mass has not been altered by MT in its past, we model the companion as an isolated star using a modified version of the stellar evolution code EZ (originally developed by Paxton 2004).

We calculate the evolution of our stellar models at solar metallicity, which is the same metallicity that Orosz et al. (2011) used in deriving the properties of the BH companion. When we place the companion’s observational constraints on an H-R diagram, we find that the current location of the companion does not seem to be consistent with any evolutionary tracks calculated by the stellar evolution code. As shown in Figure 1, the companion is overluminous for a star of its mass. This cannot be explained by earlier MT from the BH progenitor to the companion. Braun & Langer (1995) studied the effects of mass accretion onto massive main-sequence stars and found that the accreting stars would not appear overluminous for their new masses during the rest of their main-sequence lifetime. If mass accretion leads to a so-called rejuvenation of the accreting star, which means its central hydrogen abundance substantially increases, it would have the same luminosity as a star of its new mass. If rejuvenation does not occur, the accreting star would appear underluminous for its new mass during the rest of its main-sequence lifetime. One possible solution for matching the observed companion’s luminosity is increasing the core overshooting parameter \( \alpha_{ov} \) to \( \sim 0.45 \). Although this value is relatively high, it is not unphysical. Claret (2007) compared the data from 13 double-line eclipsing binary systems with theoretical predictions of stellar modeling and found \( \alpha_{ov} \) could be as high as 0.6 for massive stars. We vary \( \alpha_{ov} \) from 0.35 to 0.5, in steps of 0.01. We note that the need for such higher values of \( \alpha_{ov} \) in the modeling of massive stars may very well be connected to the significant presence of internal rotation and associated rotational mixing. Effectively
increasing $\alpha_{\text{ov}}$ leads to stronger internal mixing and in a way allows the stellar model to behave more like a rotating model.

Besides the observational constraints on the companion’s properties, there are three additional constraints. The first one comes from the fact that the companion is currently not overfilling its Roche lobe (Gies & Bolton 1986a). Thus, we require the stellar radius $R_2$ in our models to be

$$R_2 \leq A_{\text{orb}} r_{\text{egg}} + \Delta R,$$

where $r_{\text{egg}}$ is the effective Roche lobe radius given by Eggleton (1983). Here, we make an approximation that the orbit is circular and synchronized. The parameter $\Delta R$ is a constant accounting for the difference in the calculated stellar radii among stellar evolution codes (Valsecchi et al. 2010). We set $\Delta R$ to $2.5 R_\odot$.

Another constraint is that the calculated bolometric luminosity ($L_{\text{bol}}$) resulting from the stellar wind accretion process needs to fall within the observational range, which is $(1.17 - 2.35) \times 10^{37}$ erg s$^{-1}$. By adopting the Bondi & Hoyle (1944) accretion model and following Belczynski et al. (2008), the orbital-averaged accretion rate is given by

$$M_{\text{acc}} = -\frac{F_{\text{wind}}}{\sqrt{1 - e_{\text{orb}}^2}} \left(\frac{GM_{\text{BH}}}{V_{\text{wind}}^2}\right)^2 \frac{\alpha_{\text{wind}}}{2A_{\text{orb}}^2} \frac{M_2}{(1 + V_{\text{wind}}^2)^{3/2}}. \quad (2)$$

Here, $M_{\text{BH}}$ is the BH mass in our models, which varies within the $1\sigma$ range of the observational constraint, in steps of 0.098 $M_\odot$. Since the total mass that the BH could have accreted from its companion stellar wind is negligible, $M_{\text{BH}}$ in each evolutionary sequence is fixed throughout our analysis. $M_2$ is the wind mass-loss rate of the companion in our models. $F_{\text{wind}}$ is a parameter such that $M_{\text{acc}}$ never exceeds $-0.8M_2$, and $\alpha_{\text{wind}}$ is the accretion efficiency, which varies between 1.5 and 2.0 (Boffin & Jorissen 1988). $A_{\text{orb}}$ and $e_{\text{orb}}$ are the orbital semimajor axis and eccentricity, respectively. $A_{\text{orb}}$ is derived from the mean measured orbital period $P_{\text{orb}}$, which is

$$A_{\text{orb}} = \left[\frac{G(M_{\text{BH}} + M_2)P_{\text{orb}}^2}{4\pi^2}\right]^{1/3}, \quad (3)$$

where $M_2$ is the companion mass in our models. $e_{\text{orb}}$ is set equal to the mean measured orbital eccentricity. $V_{\text{wind}}$ denotes the wind velocity. $V_{\text{wind}}^2$ equals to $V_{\text{BH}}^2/V_{\text{wind}}^2$, where $V_{\text{BH}}$ is the orbital velocity square of the BH and is approximated as $G(M_{\text{BH}} + M_2)/A_{\text{orb}}$. We adopt the spherically symmetric wind velocity law given in Lamers & Cassinelli (1999),

$$V_{\text{wind}}(r) = V_{\text{esc}} + (V_\infty - V_{\text{esc}}) \left(1 - \frac{r^2}{R^2}\right)^{\beta}, \quad (4)$$

where $r$ is the distance from the companion to the BH and is set equal to $A_{\text{orb}}$. $\beta$ is a free parameter varying from 0.6 to 1.6 (Gies & Bolton 1986b; Lamers & Leitherer 1993), in steps of 0.1. $V_\infty$ is the wind velocity at infinity, while $V_{\text{esc}}$ is the effective escape velocity at the surface of the companion. Within the typical range of O star surface temperature, $V_{\text{esc}}$ is scaled as $2.65V_{\text{esc}}$ (Kudritzki & Puls 2000). Following Lamers & Cassinelli (1999),

$$V_{\text{esc}} = \sqrt{2(1 - \Gamma_e)GM_{\text{BH}}/R_2}, \quad (5)$$

where

$$\Gamma_e = \frac{\sigma_e L_2}{4\pi c G M_2} \quad (6)$$

is the mass correcting factor for the radiative force due to electron scattering, and $c$ is the speed of light in vacuum. Lamers & Leitherer (1993) scaled the electron scattering coefficient per unit mass $\sigma_e$ as

$$\sigma_e = 0.401 \left(\frac{1 + q\epsilon}{1 + 3\epsilon}\right), \quad (7)$$

where $q$ is the fraction of He$^+ + (1 - q)$ is the fraction of He$^+$, with $q = 1$ if $T_{\text{eff}} \geq 35,000$ K, $q = 0.5$ if $30,000$ K $\leq T_{\text{eff}} < 35,000$ K, and $q = 0$ if $T_{\text{eff}} < 30,000$ K. The abundance ratio $\epsilon = \text{He}/(\text{H} + \text{He})$ is fixed at 0.15, which is appropriate for an O star with a spectral type of Class I. Using $M_{\text{acc}}$ from Equation (2), we follow Belczynski et al. (2008) and calculate the bolometric luminosity resulting from the companion’s stellar wind being accreted onto the BH as

$$L_{\text{bol}} = \frac{1}{2} \frac{GM_{\text{BH}}M_{\text{acc}}}{R_{\text{acc}}}, \quad (8)$$

where $R_{\text{acc}}$ denotes the radius of the accretor. For the case of BH, $R_{\text{acc}}$ is the radius of the inner most stable circular orbit, which we calculate with Equation (2.21) in Bardeen et al. (1972). Given the observationally inferred spin $a_0 > 0.95$ (Gou et al. 2011), we adopt the median $a_0 = 0.97$ and find

$$R_{\text{acc}} = 2.57 \left(\frac{M_{\text{BH}}}{M_\odot}\right) \text{ km}. \quad (9)$$

This calculated $L_{\text{bol}}$ needs to fall within the observational range.
The Astrophysical Journal, 747:111 (12pp), 2012 March 10

WONG ET AL.

Figure 2. Systemic behavior of two selected evolutionary sequences, which have the same \( \alpha_{\text{ov}} = 0.44 \), \( M_{\text{BH}} = 14.81 \, M_\odot \), \( \alpha_{\text{wind}} = 1.5 \), and \( \beta = 1.0 \). Sequences 1 (solid) and 2 (dashed) have \( M_{z,\text{zams}} \) of 21 and 22 \( M_\odot \), respectively. The left panel shows the evolutionary tracks on the H-R diagram, while the middle panel illustrates the behaviors of the mass and the radius of the star. The right panel shows the variations of the calculated stellar luminosity and \( f_L \), where \( f_L \) is defined in Equation (10). The gray-shaded areas represent the observational constraints on the relevant quantities, and the thick part of the evolutionary tracks indicates the part of the sequence that the observational constraints on the H-R diagram are satisfied.

The last additional constraint is that the observational constraints on \( L_2 \) and \( L_{\text{bol}} \) have to be evaluated at the same distant estimation. To examine this, we calculate the ratio

\[
f_L = \left( \frac{L_2}{10^5 L_\odot} \right) \left( \frac{L_{\text{bol}}}{10^{37} \text{ erg s}^{-1}} \right)^{-1},
\]

(10)

which is independent of distance. From Figure 1 in Orosz et al. (2011), \( L_2 \) is \( 2.09 \times 10^5 L_\odot \) at \( T_{\text{eff}} = 30,000 \, \text{K} \), and is \( 2.51 \times 10^5 L_\odot \) at \( T_{\text{eff}} = 32,000 \, \text{K} \), assuming a distance of 1.86 kpc. Together with the measured range of \( L_{\text{bol}} \) rescaled at the same distance estimation, the upper and lower limits of \( f_L \) are 1.01 and 1.90, respectively. We can assure that both luminosity constraints are evaluated at the same distance estimation if \( f_L \) falls within that range.

In order to find the current evolutionary stage of the BH companion, we apply these constraints to a set of evolutionary sequences, which cover the parameter space of the companion’s ZAMS mass \( (M_{z,\text{zams}}) \), \( \alpha_{\text{ov}}, M_{\text{BH}}, \alpha_{\text{wind}} \), and \( \beta \). For each sequence, we find whether there exists a point in time that the calculated properties simultaneously satisfy all observational constraints: the BH companion’s mass, luminosity, temperature, and radius, \( L_{\text{bol}}, f_L \), and not overfilling the Roche lobe of the BH companion. Similar to the Roche lobe constraint, we also consider an uncertainty of \( \pm 2.5\, R_\odot \) in the calculated stellar radii when we apply the observational constraint of the BH companion’s radius. If such a period of time exists, we classify that evolutionary sequence as “successful.” The behavior of some relevant parameters is illustrated in Figure 2 for two selected successful sequences that are chosen mainly to provide a clear and instructive picture. The displayed sequences therefore do not represent our best possible matches to the observed properties of Cygnus X-1. Figure 3 shows the parameter space of \( M_{z,\text{zams}}, \alpha_{\text{ov}}, \text{ and } M_{\text{BH}} \) covered by all successful sequences. For \( \alpha_{\text{wind}} \) and \( \beta \), the successful sequences covered the entire allowed parameter space, which are \( 1.5 \leq \alpha_{\text{wind}} \leq 2.0 \) and \( 0.6 \leq \beta \leq 1.6 \).

The current age of the BH companion could be derived from the time interval at which all observational constraints are satisfied. Assuming that the BH progenitor and its companion formed at the same time, we could compute the time since the BH formation \( (t_{\text{sys}}) \) by

\[
t_{\text{sys}} = t - t_{\text{BH}},
\]

(11)

where \( t_{\text{BH}} \) is the approximate lifetime of the BH progenitor. We follow Belczynski et al. (2010) to calculate \( M_{\text{BH}} \) and \( t_{\text{BH}} \) for different progenitors using the stellar evolution code SSE (Hurley et al. 2000), and adopting the mass-loss prescriptions which were classified as “Vink et al. winds.” The calculated \( t_{\text{BH}} \) are fit as a function of \( M_{\text{BH}} \),

\[
\frac{t_{\text{BH}}}{10^6 \text{ yr}} = \frac{M_{\text{BH}}}{M_\odot} \left( \frac{M_{\text{BH}}}{M_\odot} \right)^{2/3} + 3.341
\]

(12)

for \( M_{\text{BH}} \geq 9.5 \, M_\odot \). Figure 4 shows the variations of \( t_2 \) and \( t_{\text{BH}} \) against \( M_{z,\text{zams}} \). We find that \( t_{\text{sys}} \) is between 4.8 and 7.6 Myr.
the Galactic plane and the end points of all trajectories fall within 110 pc from the Galactic plane, we consider each end point as a possible birth site of the BH. The post-SN peculiar velocity \( v_{\text{postSN}} \) of the binary is obtained by subtracting the local Galactic rotational velocity from the center-of-mass velocity of the binary at the birth sites. We find \( v_{\text{postSN}} \) ranges from 22 to 32 km s\(^{-1}\) and is time independent. The distribution of \( v_{\text{postSN}} \) against the time expired since the formation of the BH are displayed in Figure 5.

6. ORBITAL DYNAMICS AT CORE COLLAPSE

For each successful sequence, we perform a Monte Carlo simulation which consists of 20 million pre-SN binaries. The properties of the BH progenitor’s companion are taken from the stellar model of that sequence, at the time when the age of the star is equal to \( t_{\text{BH}} \). During a supernova (SN) explosion, the mass loss from the system and possibly the kick imparted to the BH change the binary’s orbital parameters. The pre- and post-SN component masses, orbital semimajor axis, and orbital eccentricity are related by the conservation laws of the orbital energy and angular momentum. In the following, we add the subscripts “preSN” and “postSN” to the notation of the orbital elements to distinguish between their values just prior to, and right after, the SN explosion that formed the BH.

We start with seven free parameters: the BH immediate (He-rich) progenitor mass \( (M_{\text{He}}) \), pre-SN orbital semimajor axis \( (A_{\text{preSN}}) \) and eccentricity \( (e_{\text{preSN}}) \), the mean anomaly \( (m) \), the magnitude \( (V_k) \), and direction \( (\theta, \phi) \) of the kick velocity imparted to the BH. \( \theta \) is the polar angle of the kick with respect to the relative orbital velocity of the BH progenitor just prior to the SN explosion, and \( \phi \) is the corresponding azimuthal angle (see Figure 1 in Kalogera 2000 for a graphical representation). The first five parameters are drawn from uniform distributions, while the last two are drawn from isotropic distributions. It is obvious that the progenitor must of course be more massive than the BH, but there is no absolute upper limit for the progenitor mass. We adopt \( M_{\text{He}} < 20 M_\odot \), and provide a discussion on this upper limit in Section 9.1.

The relations between pre- and post-SN parameters have been derived by Hills (1983):

\[
V_k^2 + V_{\text{He,preSN}}^2 + 2V_k V_{\text{He,preSN}} \cos \theta = G(M_{\text{BH}} + M_z) \times \left( \frac{2}{r} - \frac{1}{A_{\text{postSN}}} \right),
\]

\[
G(M_{\text{BH}} + M_z) A_{\text{postSN}} (1 - e^2_{\text{postSN}}) = r^2 (V_k^2 \sin^2 \theta \cos^2 \phi + \sin \psi (V_{\text{He,preSN}} + V_k \cos \theta) - V_k \cos \psi \sin \theta \sin \phi^2).
\]

Here, \( r \) is the orbital separation between the BH progenitor and its companion at the time of SN explosion,

\[
r = A_{\text{preSN}} (1 - e_{\text{preSN}} \cos E_{\text{preSN}}),
\]

where \( E \) is the eccentric anomaly and is related to \( m \) as

\[
m = E - e \sin E.
\]
Figure 5. Upper panels: the gray dots illustrate the possible locations of Cygnus X-1 at the birth time of the BH, obtained from 3000 integrations of its trajectory backward in time. The initial conditions of the integrations are generated randomly using the methodology described in Section 5. The plus signs indicate the current location of Cygnus X-1, derived from the mean distance of 1.86 kpc. The crosses represent the current location of Cyg OB3 center, with an adopted distance of 2 kpc. Lower panel: the distribution of post-SN peculiar velocities $V_{\text{pec}, \text{postSN}}$ against the time expired since the BH formation.

$V_{\text{He}, \text{preSN}}$ is the relative pre-SN orbital velocity of the BH progenitor,

$$ V_{\text{He}, \text{preSN}} = \left[ G(M_{\text{He}} + M_2) \left( \frac{2}{r} - \frac{1}{A_{\text{preSN}}} \right) \right]^{1/2}. $$

(17)

The angle $\psi$ is the polar angle of the position vector of the BH with respect to its pre-SN orbital velocity in the companion’s frame. It is related to the pre-SN parameters as

$$ r^2 V_{\text{He}, \text{preSN}}^2 \sin^2 \psi = G(M_{\text{He}} + M_2) A_{\text{preSN}} (1 - e_{\text{preSN}}^2). $$

(18)

Since the core collapse is instantaneous, $r$ remains unchanged. This gives a constraint

$$ r = A_{\text{preSN}} (1 - e_{\text{preSN}} \cos E_{\text{preSN}}) = A_{\text{postSN}} (1 - e_{\text{postSN}} \cos E_{\text{postSN}}), $$

(19)

which needs to be satisfied with $| \cos E_{\text{postSN}} | \leq 1$.

The mass loss from the system and a natal kick imparted to the BH can induce a post-SN peculiar velocity ($V_{\text{pec, postSN}}$) at the binary’s center of mass. Its magnitude is determined by Equations (28)–(32) in Paper I and is required to fall within the range derived in Section 5, which is 22–32 km s$^{-1}$.

In addition, there are two more restrictions on the properties of pre- and post-SN binary components. First, we require that both components have to fit within their pre- and post-SN Roche lobe at periapsis. We impose this condition to avoid complications arising from MT-induced changes in the stellar structure of the MS companion that later becomes the BH companion of the XRB. To calculate the Roche lobe radius of each component in eccentric pre- and post-SN orbits, we adopt the fitting formulae of Sepinsky et al. (2007). When calculating the pre-SN Roche lobe radii, we assume that the pre-SN orbit is pseudo-synchronized. Again, due to the difference in calculated stellar radii among stellar evolution codes, we consider an uncertainty of $\pm 2.5 R_\odot$ on the companion radius (Valsecchi et al. 2010). The radius of the BH immediate progenitor can be approximated by Equations (3) in Fryer & Kalogera (1997), since we assume that it is a Helium star. Second, the pre-SN spin of the BH immediate progenitor and its companion need to be less than the breakup angular velocity $\Omega_c \approx (GM/R_3)^{1/2}$. As the calculated stellar radius $R_2$ associates with an uncertainty $\Delta R = 2.5 R_\odot$ (Valsecchi et al. 2010),

$$ \Omega_c = \sqrt{\frac{GM_2}{R_2^3}} \left( 1 + \frac{3 \Delta R}{2 R_2} \right). $$

(20)

for the BH companion.

7. ORBITAL EVOLUTION AFTER THE SN EXPLOSION

The orbital evolution of the simulated binaries, which are generated from the Monte Carlo simulations described in Section 6, is calculated up to the current epoch. After the formation of the BH, the orbital parameters of the binary are subject to secular changes due to the tidal torque exerted by the BH on its companion, and due to the loss of orbital angular momentum via gravitational radiation and stellar wind. Since the tidal interactions depend on both the orbital and rotational properties of the MS companion, the star’s rotational angular velocity ($\Omega$) right after SN explosion that formed the BH enters the problem as an additional unknown quantity. Here, we assume the rotational angular velocity of the BH companion
is unaffected by the SN explosion and is pseudo-synchronized to the pre-SN orbital frequency. The system of equations governing the tidal evolution of the orbital semimajor axis $A$, eccentricity $e$, and the BH companion’s rotational angular velocity $\Omega$ has been derived by Hut (1981):

$$\left(\frac{dA}{dt}\right)_{\text{tides}} = -\frac{k_2 M_{\text{BH}} M_{\text{BH}} + M_2}{T M_2^2 M_2^2} \left(\frac{R_2}{A}\right)^8 \frac{A}{(1-e^2)^{5/2}} \times \left[ f_1(e^2) - (1-e^2)^{3/2} f_2(e^2) \frac{\Omega}{n}\right],$$

(21)

$$\left(\frac{de}{dt}\right)_{\text{tides}} = -27 \frac{k_2 M_{\text{BH}} M_{\text{BH}} + M_2}{T M_2^2 M_2^2} \left(\frac{R_2}{A}\right)^8 \frac{e}{(1-e^2)^{13/2}} \times \left[ f_3(e^2) - \frac{11}{18} (1-e^2)^{3/2} f_4(e^2) \frac{\Omega}{n}\right],$$

(22)

$$\left(\frac{d\Omega}{dt}\right)_{\text{tides}} = \frac{3 k_2}{T} \left(\frac{M_{\text{BH}}}{M_2}\right) \frac{2 M_2 R_2^2}{I_2} \left(\frac{R_2}{A}\right)^6 \frac{n}{(1-e^2)^6} \times \left[ f_5(e^2) - (1-e^2)^{3/2} f_6(e^2) \frac{\Omega}{n}\right].$$

(23)

Here, $k_2$ and $I_2$ are the apsidal-motion constant and moment of inertia of the MS companion, respectively. $T$ is a characteristic timescale for the orbital evolution due to tides and $n = 2\pi/\Phi_{\text{orb}}$ is the mean orbital angular velocity. The coefficient functions $f_i(e^2)$ for $i = 1, 2, \ldots, 5$ are given in Equations (11) in Hut (1981). As the BH companion in Cygnus X-1 is a massive MS star with a radiative envelope, the factor $k_2/T$ can be approximated as

$$\left(\frac{k_2}{T}\right)_{\text{rad}} = 1.9782 \times 10^4 \left(\frac{R_2}{R_\odot}\right) \left(\frac{R_\odot}{A}\right)^{5/2} \left(\frac{M_2}{M_\odot}\right)^{1/2} \times \left(\frac{M_{\text{BH}} + M_2}{M_2}\right)^{5/6} E_2 \text{yr}^{-1}.$$  

(24)

The constant $E_2$ comes from a fit to the tables in Claret (2004),

$$\log E_2 = -\frac{t/t_{\text{ms}}}{2.20489 - 1.89579(t/t_{\text{ms}})} - 5.51039,$$  

(25)

for $15.85 \leq M_{\text{zams}} \leq 25.12 M_\odot$. Here, $t_{\text{ms}}$ is the main-sequence lifetime. We define the end of the main sequence as the hydrogen abundance at the core being less than 0.01.

To follow the secular changes of the orbital parameters associated with emissions of gravitational waves, we adopt Equations (35) and (36) in Junker & Schäfer (1992), which are derived up to 3.5 post-Newtonian order.

The rates of change in $A$ and $e$ due to wind mass loss and wind accretion onto the BH are determined by following Equations (15) and (16) in Hurley et al. (2002),

$$\left(\frac{dA}{dt}\right)_{\text{wind}} = -A \left[ \frac{M_2}{M_{\text{BH}} + M_2} + \frac{2 - e^2}{M_{\text{BH}}} + \frac{1 + e^2}{M_{\text{BH}} + M_2} \right] \times \frac{M_{\text{acc}}}{1-e^2},$$

(26)

$$\left(\frac{de}{dt}\right)_{\text{wind}} = -e M_{\text{acc}} \left(\frac{1}{M_{\text{BH}} + M_2} + \frac{1}{2 M_{\text{BH}}}\right),$$

(27)

The mass loss via stellar wind also induces a loss in the spin angular momentum of the BH companion. Hurley et al. (2000) showed that if all the mass is lost uniformly from a thin shell at the surface of the MS star,

$$J_{\text{2,spin}} = \frac{d}{dt} (I_2 \Omega) = \frac{2}{3} M_2 R_2^2 \Omega,$$  

(28)

where $J_{\text{2,spin}}$ is the spin angular momentum of the BH companion.

For each of simulated binaries, we follow the secular changes of its orbital properties due to all the mechanisms mentioned in this section. The properties of binary components are adopted from the corresponding successful sequence. Unlike finding $V_{\text{pec, postSN}}$ in Section 5, the orbital evolution of the binary goes forward in time, from $t_{\text{BH}}$ to $t_2$. Within this period of time, the BH companion has to always fit within its Roche lobe at periapsis. In other words, its calculated radius is constrained to be less than the Roche lobe radius at periapsis given by Seipinsky et al. (2007). Again, we allow an uncertainty of $\pm 2.5 R_\odot$ due to the difference in calculated stellar radii among stellar evolution codes (Valsecchi et al. 2010). Furthermore, the rotational angular velocity of the BH companion has to be smaller than the breakup angular velocity $\Omega_b$. If the orbital period and eccentricity of the simulated binary at $t_2$ match the measured values of Cygnus X-1, we classify that binary as a “winning binary.” Figure 6 illustrates the time evolution of orbital parameters for one selected winning binary and shows that the change in the semimajor axis is mainly determined by the stellar wind mass loss, while the change in the eccentricity is overwhelmingly dominated by the tidal effects.

8. PROGENITOR CONSTRAINTS

The elements presented in the previous sessions can now be combined to establish a complete picture of the evolution of Cygnus X-1 and the dynamics involved in the core-collapse event that formed the BH. After finding the successful evolutionary sequences that satisfy all the observed properties of the BH companion and the bolometric X-ray luminosity, as discussed in Section 4, we trace the motion of the system in the Galaxy back in time to the formation of the BH. We adopt the methodology of Gualandris et al. (2005) to account for the uncertainties in the measured distance and velocity components of Cygnus X-1. The time of BH formation is different for each successful sequence. It is estimated by the BH mass of the sequence, which connects to an approximate lifetime of the corresponding BH progenitor. This procedure gives us a constraint on the system’s peculiar velocity right after the BH formation. We then perform Monte Carlo simulations on the orbital dynamics at core collapse for each successful sequence. There are seven free parameters: the BH immediate progenitor mass, the pre-SN orbital semimajor axis and eccentricity, the mean anomaly, the magnitude of kick velocity imparted to the BH, and the two angles specifying the direction of the kick velocity. The Monte Carlo simulations produce a population of simulated binaries, which satisfy the post-SN system’s peculiar velocity constraint derived already. Lastly, we evolve the orbits of these simulated binaries forward in time to the current epoch. If the orbital period and eccentricity of the simulated binary at current epoch match the measured values of Cygnus X-1, we classify that simulated binary as a “winning binary.” The results presented in what follows are derived from the winning binaries of all successful sequences.
In Figure 7, we present the probability distribution functions (PDFs) of the BH immediate (He-rich) progenitor mass ($M_{\text{He}}$) and natal kick magnitude ($V_{\text{k}}$). We find $M_{\text{He}}$ to be in a range of 15.0–20.0 $M_{\odot}$, and $V_{\text{k}}$ to be $\leq 77$ km s$^{-1}$, both at 95% confidence. Figure 8 illustrates the two-dimensional joint $V_{\text{k}}$–$M_{\text{He}}$ confidence levels, which shows that if $M_{\text{He}}$ is less than $\sim 17$ $M_{\odot}$, the BH might have received a non-zero natal kick at the core-collapse event. For small $M_{\text{He}}$, a minimum $V_{\text{k}}$ of $\sim 55$ km s$^{-1}$ is necessary for explaining the current observed properties of Cygnus X-1. Furthermore, both the $M_{\text{He}}$ PDF and the two-dimensional joint $V_{\text{k}}$–$M_{\text{He}}$ confidence levels show that the maximum $M_{\text{He}}$ is constrained by our adopted upper limit of 20 $M_{\odot}$. We impose this limit based on the physics involved in the evolution of massive stars. A discussion on this limit can be found in Section 9.1. Given our understanding of mass loss from Helium stars, it seems that the BH has potentially received a small natal kick velocity of $\leq 77$ km s$^{-1}$ (95% confidence) during the core-collapse event.

Based on the dynamical model of Orosz et al. (2011), Gou et al. (2011) found that the BH in Cygnus X-1 has a spin...
through the Galactic potential right after the BH formation, and the binary orbital dynamics at the time of core collapse. We find that the mass of the BH immediate progenitor falls within a range of $15.0-20.0 \ M_\odot$ at 95% confidence. We note that the maximum progenitor mass is constrained by our adopted upper limit, which is discussed in Section 9.1. The BH has potentially received a small natal kick velocity of $\lesssim 77 \ km \ s^{-1}$ at 95% confidence. In fact, if the progenitor mass is less than $\sim 17 \ M_\odot$, a non-zero natal kick velocity is necessary to explain the currently observed properties of Cygnus X-1. Since the BH has only accreted mass from its companion’s stellar wind, the total amount of mass accreted since the BH formation is less than $\sim 2 \times 10^{-3} \ M_\odot$. This indicates that the observationally inferred BH spin of $a_\star > 0.95$ (Gou et al. 2011) cannot be explained by mass accretion and has to be natal. This high spin has implications for BH formation and the role of rotation in core collapse. Right after the BH formation, the BH companion has a mass of $19.8-22.6 \ M_\odot$, in an orbit with period of $4.7-5.2$ days and eccentricity of $0.015-0.022$. Although the post-SN orbital eccentricity is small, the pre-SN orbit can potentially be fairly eccentric. This is possible if the BH receives a natal kick velocity at the right magnitude and direction.

The formation of the BH in Cygnus X-1 has been previously studied by Nelemans et al. (1999) and Mirabel & Rodrigues (2003). Both studies assumed symmetric mass loss during the core-collapse event and considered only the binary orbital dynamics at the time of core collapse. Comparing with these two earlier studies, we consider the possible asymmetries developed during the core-collapse event and the evolution of the binary since the BH formation. It is important to note that these two earlier studies do not consider the multitude of the observational constraints taken into account here and hence the suggested progenitors are not complete solutions for the evolutionary history of Cygnus X-1.

Finally, we discuss some of the assumptions introduced in our analysis in the following subsections.

9.1. Maximum BH Progenitor Mass

Unlike the case of GRO J1655-40 studied in Paper I, the analysis of orbital dynamics during the core-collapse event does not give an upper limit on $M_{\text{He}}$. Instead, we have conservatively adopted an upper limit of $M_{\text{He}} \lesssim 20 \ M_\odot$, based on physics involved in the evolution of massive stars. As mentioned in Section 6.1 of Paper II, by evolving a ZAMS star of $\sim 100 \ M_\odot$ at solar metallicity, the maximum Helium star mass one can achieve is $\sim \ 15 \ M_\odot$ when including moderate stellar rotation, and $\sim 17.5 \ M_\odot$ when assuming no stellar rotation. When adopting the upper limit of 17.5 $M_\odot$, the lower limit of $M_{\text{He}}$ decreases slightly to 14.6 $M_\odot$ and the range of $V_\text{K}$ becomes $14-81 \ km \ s^{-1}$, both with 95% confidence. This range of $V_\text{K}$ still suggests that the BH in Cygnus X-1 received a low kick during the core-collapse event.

9.2. Association with Cyg OB3

The center of Cyg OB3 locates at $l = 72.8$ and $b = 2.0$, and at a distance of $1.4-2.7$ kpc away from the Sun (Massey et al. 1995; Dambis et al. 2001; Mel’nik et al. 2001; Mel’nik & Dambis 2009). When comparing that to the location of Cygnus X-1 (Table 1), it is clear that not only are their Galactic coordinates close to each other, but also their distance estimations overlap with each other. Furthermore, the measurements of proper motion and radial velocity show that Cygnus X-1 is moving

![Figure 9](image.png)

Figure 9. Two-dimensional joint $A_{\text{preSN}} - e_{\text{preSN}}$ confidence levels: 68.3% (red), 95.4% (yellow), and 99.7% (blue).

(A color version of this figure is available in the online journal.)

parameter $a_\star > 0.95$ at 3$\sigma$. To determine whether the BH was born with an extreme spin, we first estimate how much mass the BH could have accreted from its companion’s stellar wind since the time of BH formation. The winning binaries of all successful sequences show that at maximum the BH has accreted $\sim 2 \times 10^{-3} \ M_\odot$. Since it is impossible to spin the BH up to $a_\star > 0.95$ by accreting that negligible amount of mass, the BH needs to have an extreme spin at birth. This high spin has implications about BH formation and the role of rotation in core collapse. Axelsson et al. (2011) also concluded that the observed spin connects to processes involved in core collapse and is not likely to originate from the synchronous rotation of the BH progenitor.

Besides the constraints on the BH formation, our results also shed light on the evolutionary picture of Cygnus X-1. We find that right after the formation of the BH, the BH companion has a mass of $19.8-22.6 \ M_\odot$, in an orbit with period of 4.7–5.2 days. Since then, the orbital separation of Cygnus X-1 has been increasing with time, as the rate of change in the semimajor axis is dominated by the influence of stellar wind mass loss from the system. On the other hand, the orbital eccentricity has decreased slightly since the BH formation. This is because the tides exerted on the companion by the BH, as the dominant mechanism of circularizing the orbit, are not strong enough to decrease the orbital eccentricity significantly within the time period of several million years since the time of BH formation. We find that $e_{\text{postSN}}$ ranges from 0.015 to 0.022. However, this does not suggest that $e_{\text{preSN}}$ has to be small. An eccentric pre-SN orbital could become fairly circular if there is a natal kick imparted to the BH at the right direction. As illustrated in Figure 9, there are winning binaries with $e_{\text{preSN}}$ being as high as $\sim 0.53$.

9. SUMMARY AND DISCUSSION

In this paper, we constrained the progenitor properties and the formation of the BH in the persistent XRB Cygnus X-1. Our analysis accounts for the orbital evolution and motion
as the members of Cyg OB3 (Dambis et al. 2001; Mirabel & Rodrigues 2003; Mel’Nik & Dambis 2009). Based on these observations, Mirabel & Rodrigues (2003) argue that Cyg OB3 is the parent association of Cygnus X-1. This infers that \( V_{\text{pec,postSN}} \) due to the core-collapse event has to be small. If we change the constraint on \( V_{\text{pec,postSN}} \) to \( \lesssim 10 \text{ km s}^{-1} \), we find \( M_{\text{He}} \) to be in a range of \( 13.9–16.9 \ M_\odot \) and \( V_k \) to be \( \lesssim 24 \text{ km s}^{-1} \), both at 95% confidence. Besides the change in 95% limits, non-zero BH natal kicks are not needed for progenitors of \( M_{\text{He}} \leq 17 \ M_\odot \) in order to explain the observed properties of Cygnus X-1, but become necessary for \( M_{\text{He}} > 17.5 \ M_\odot \) (see Figure 10). Also, we note that a relatively small change on the range of \( V_{\text{pec,postSN}} \) affects the derived constraint on \( V_k \) qualitatively.

### 9.3. Super-synchronized Orbit

After considering several previous measurements of the BH companion’s surface rotation speed \( V_{\text{rot}} \sin i \), Caballero-Nieves et al. (2009) adopted \( V_{\text{rot}} \sin i = 95 \pm 6 \text{ km s}^{-1} \). Orosz et al. (2011) found that the ratio of the BH companion’s spinning frequency to the orbital frequency (\( f_{\Omega} \)) was \( 1.400 \pm 0.084 \), which was derived based on their results of the inclination angle \( i = 27.06 \pm 0.76 \) and the companion radius \( R_2 = 16.5 \pm 0.84 \). This indicates that the BH companion is super-synchronized. We note that with the analysis presented here, we find that none of our winning binaries have super-synchronized BH companions at the current epoch. They are all sub-synchronized with \( f_{\Omega} \) reaching \( \sim 0.87 \) at maximum.

In an effort to examine how our standard assumptions can be modified and to investigate whether super-synchronism is at all allowed by the models as indicated by the observations, we make two modifications to our analysis. We first remove the assumption that the pre-SN orbit is pseudo-synchronized, and randomly distribute the pre-SN spin of the BH companion between zero and its breakup angular frequency \( \Omega_0 \). Next, we reduce the secular changes of the orbital parameters due to the influence of tides by multiplying the right-hand side of Equations (21)–(23) by a constant \( f_{\text{tide}} \).

As shown in Figure 11, by allowing the pre-SN spin of companion to be greater than pseudo-synchronization and keeping the tidal strength unchanged (i.e., \( f_{\text{tide}} = 1.0 \)), the maximum \( f_{\Omega} \) of the winning binaries increases to \( \sim 1.2 \). Although it is getting close, this value is still below the observationally inferred one. Together with a weakened tidal strength of \( f_{\text{tide}} = 0.2 \) and 0.5, we comfortably find winning binaries with \( f_{\Omega} = 1.4 \). Furthermore, the minimum pre-SN surface rotation speed of the companion in those winning binaries are \( \sim 500 \) and \( 700 \text{ km s}^{-1} \) for \( f_{\text{tide}} = 0.2 \) and 0.5, respectively. Given the uncertainties in the physics of fast rotating massive stars, it seems that super-synchronism in Cygnus X-1 is allowed by our presented models, if the companion is spinning faster than orbital pseudo-synchronization right before the core-collapse event and the tides exerted on the companion are weaker than the nominal theoretical values.

### 9.4. Constraints on the BH Kick Direction

Since the measured eccentricity of Cygnus X-1 is very low (see Table 1), and the orbit has not been circularized much since the formation of the BH (see Figure 6), \( e_{\text{postSN}} \) has to be very small too. As discussed in Section 8, we indeed find that \( e_{\text{postSN}} \) falls within a range of \( 0.015–0.022 \). From the orbital dynamics at core collapse, the very low \( e_{\text{postSN}} \) might shed light on the properties of the natal kick imparted to the BH.

During the core-collapse event, \( e_{\text{postSN}} \) is affected by the amount of mass loss, the direction and magnitude of the natal kick, as well as \( \epsilon_{\text{presSN}} \). As mass loss tends to increase the eccentricity, a natal kick in the right direction and magnitude is needed in order to counteract the effect of mass loss and result in a very low \( e_{\text{postSN}} \). It turns out that with the observationally inferred constraints on \( M_{\text{BH}}, M_2, V_{\text{pec,postSN}} \), and the extra constraints mentioned in Section 6, the eccentricities right after...
symmetric explosions (i.e., no natal kicks) are typically $\sim 0.1$, and overwhelmingly $< 0.45$. Also, the difference between pre- and post-SN eccentricities is mostly $< 0.15$. These link to the requirement of the small $V_{\text{pec,postSN}}$. Larger amounts of mass loss relative to the total mass of the pre-SN system not only leads to higher $e_{\text{postSN}}$, but also larger $V_{\text{pec,postSN}}$, and hence they are not allowed. For the same reason, the required kick velocity for getting the very low post-SN eccentricity also needs to be small. In addition, we note that under special conditions, $e_{\text{postSN}}$ could be low even though $e_{\text{preSN}}$ is high. Hills (1983) showed that if the symmetric supernova explosion occurs at the proximity of apastron, $e_{\text{postSN}}$ could be $\sim 0$ for a specific range of mass loss.

As the eccentricity induced by mass loss is low, natal kicks do not have to contribute dramatically to make $e_{\text{postSN}}$ fall within the observationally required range. Although natal kicks have to be constrained in some directions, that constraint is not so super narrow. By extracting data from the winning binaries, we found that 70% have $\cos(\theta) < 0$; the distribution in the azimuthal angle $\phi$ for the kicks of the winning binaries does not deviate much from the a priori flat distribution. As a result, the requirement of a very low $e_{\text{postSN}}$ does constrain the natal kick directions, but the constraint is not particularly strong.
