ABSTRACT

\textbf{Aims.} Our goal is to research the upper limits to the extragalactic background light (EBL).

\textbf{Methods.} The upper limits to the extragalactic background light (EBL) are presented, using the Fermi and very high energy (VHE) spectra recently observed in TeV blazars. We use an assumption that the VHE intrinsic photon index cannot be harder than the Fermi index measured by the Fermi-LAT.

\textbf{Results.} These upper limits are compatible with ones given by most EBL models; however, the models of high EBL density are contradicted by TeV blazars.

\textbf{Key words.} gamma rays: galaxies – BL Lacertae objects: general – diffuse radiation

1. Introduction

The diffuse extragalactic background light (EBL) consists of the sum of the starlight emitted by galaxies through the history of the Universe and includes an important contribution from the first stars. Direct measurements of the extragalactic background light (EBL) from the infrared (IR) to the ultraviolet (UV) are difficult because of the light pollution of bright foreground sources (see comprehensively reviewed measurements and implications of the cosmic infrared background, Hauser & Dwek 2001). The method of galaxy counts is used to estimate the EBL, but it only provides a lower limit owing to the unknown of unresolved sources. Various models for the EBL have been published: Salamon & Stecker (1998), Malkan & Stecker (1998, 2001), Stecker et al. (2006), Kneiske et al. (2002, 2004), Primack et al. (2005, 2008), Gilmore et al. (2008, 2009), Franceschini et al. (2008), Razzaque et al. (2009), Finke et al. (2010). These models include different degrees of complexity, observational constraints, and data inputs.

Absorption features imprinted on the very high-energy (VHE) spectra of distant extragalactic objects by background light photons provide an indirect approach to studying the EBL. Assuming an intrinsic gamma-ray spectrum, Stecker & de Jager (1993) and Stanek & Franceschini (1998) have constrained the EBL from the observed VHE spectra of blazars. Aharonian et al. (2006a) also discuss the upper limits on the background light at optical/near-infrared wavelengths based on the HESS observation of 1ES 1101-232. They assume that the intrinsic spectrum is not harder than \( \Gamma_{\text{int}} = 1.5 \) and put limits on EBL quite close to the lower limits by galaxy counts. The detailed studies of EBL shapes and blazar VHE spectra are also given by Mazin & Raue (2007), Schroeder (2005), and Finke & Razzaque (2009) where the same intrinsic spectrum is assumed for all blazars. In fact, blazars have different intrinsic spectra. The main handicap of this approach to limiting EBL is the uncertainty about the intrinsic spectrum of VHE.

To date, 35 AGN sources have been detected at TeV energies \((E > 100 \text{ GeV})\). Their observed VHE spectra have power-law shapes with the index \( \Gamma_{\text{VHE}} \geq 2 \), in which distant sources have large \( \Gamma_{\text{VHE}} \), up to 4 (e.g. Acciari et al. 2009b; Albert et al. 2007b, 2008b; Aharonian 2006c, 2005a). Many of these sources have recently been detected at GeV energies by the Fermi Gamma-ray Space Telescope (Abdo et al. 2009, 2010b). Abdo et al. (2009) have extrapolated the Fermi spectrum up to 10 TeV assuming a single spectral index and taken it as an intrinsic spectrum of VHE ranges. Most breaks of the observed VHE spectra are consistent with the absorption predicted by the minimal EBL density model. For a TeV source, a break between the Fermi and VHE energy ranges might be caused by some internal or external factors. The internal factors include a break in the emitting particle distribution or an intrinsic absorption caused by strong optical-infrared radiation within the source (Donea & Protheroe 2003). The external factors usually refer to the cosmic attenuation effect. Furthermore, it is difficult to predict the intrinsic spectrum from simultaneous multi-wavelength observations because of the complexity of the VHE emission mechanism.

In this work, we assume that the Fermi spectral index measured by Fermi-LAT is the lower limit of intrinsic VHE spectral index for TeV blazars instead of single 1.5. In the other words, the photon index from the Fermi to VHE energy range is only softened except for the presence of a new component (Yang & Wang 2010) or monochromatic radiation fields within the source (Aharonian et al. 2009). The steeper intrinsic index assumed by us provides stronger constraints on the EBL intensity. All Fermi photon indexes of TeV sources are larger than the 1.5 with the exclusion of H 1426+428 \( \Gamma_{\text{Fermi}} = 1.47 \). Moreover, when taking the differences of VHE emission between the different
sources into account, this assumption is more reasonable than assuming $\Gamma_{\text{int}} > 1.5$. Recently, Georganopoulos et al. (2010) and Mankuzhiyil et al. (2010) have also used the extrapolation of the Fermi data as upper limits on intrinsic TeV spectra. Assuming the VHE intrinsic spectra corrected by EBL absorption is softer than the Fermi spectra, Prandini et al. (2010) find that the derived redshifts are might larger than true ones. It shows that their assumption is reliable.

Based on this assumption, we analyze the Fermi and VHE spectra of TeV blazars and give upper limits for the EBL intensity. In Sect. 2 we describe the method of calculating $\Gamma_{\text{int}}$ and its standard error $\sigma(\Gamma_{\text{int}})$ assuming $\Gamma_{\text{int}}$ greater than 0.1 show $\Delta \Gamma \geq 1.5$. We assume that the observed Fermi spectral index is the lower limit of intrinsic VHE spectra. In Sect. 3 we apply the method to the TeV blazars with VHE and Fermi spectra and discuss the limits of these sources on the EBL.

2. The method

The VHE absorption of the EBL is caused by the pair production of photon-photon collisions. The observed VHE flux is given by

$$f_{\text{obs}}(E_{\gamma}) = e^{-\tau(E_{\gamma})} f_{\text{int}}(E_{\gamma}),$$

where $\tau(E_{\gamma})$ is the optical depth, $E_{\gamma}$ the observed $\gamma$-ray photon energy, and $f_{\text{int}}(E_{\gamma})$ the intrinsic flux.

For a VHE source at redshift $z_e$, the optical depth of its $E_{\gamma}$ energy photon caused by the EBL is given by

$$\tau(E_{\gamma}, z_e) = cr_e^2 \left( \frac{m_e^2 c^4}{E_{\gamma}} \right)^{1/2} \int_{z_e}^{\infty} \frac{dz'}{dz} \int_{z'}^{\infty} e^{-\tau(E_{\gamma}, \epsilon)} d\epsilon \cdot e^{-\tau_{\gamma\gamma}(\epsilon)} \delta(z_{\gamma}(\epsilon)),$$

(2)

where $n(\epsilon, z)$ is the photon number density of the EBL with energy $\epsilon$ at redshift $z$, $r_e$ is the classical electron radius, $s_0 = eE_{\gamma}/m_e^2 c^4$, $z_{\gamma}(\epsilon) = 2\epsilon/m_{e} c$ is a function given by Gould & Schréder (1967), and $\frac{dz}{dz'}$ is the differential redshift given by

$$\frac{dz}{dz'} = \frac{1}{H_0 (1 + z)} [(1 + z)^2 (1 + \Omega_m z) - z(z + 2)\Omega_k]^{-1/2}. \quad (3)$$

Abdo et al. (2009) find that the intrinsic spectra of many TeV sources can be described by a single power law across the Fermi and VHE energy ranges. In fact, the observed Fermi and VHE spectral indices are different owing the EBL absorption. Their difference $\Delta \Gamma$ increases with redshift. For example, M 87 and Cen A with low redshifts have $\Delta \Gamma \approx 0$, while blazars with redshifts greater than 0.1 show $\Delta \Gamma \geq 1.5$. We assume that the observed Fermi spectral index is the lower limit of intrinsic VHE spectral index, i.e., $\Gamma_{\text{min, VHE}} \approx \Gamma_{\text{Ferm}}$. For some objects, multiple VHE spectra have been observed in different flux states. We adopt the VHE spectra of their low flux states to constrain the EBL.

Based on $\Gamma_{\text{min, VHE}}$, an upper limit on the optical depth $\tau(E_{\gamma}, z_e)$ is given by Finke & Razzaque (2009)

$$\tau^{\text{max}}(E_{\gamma}, z_e) = \tau(E_{\gamma, \text{min}}, z_e) + \left(1 - \Gamma_{\text{min, VHE}}\right) \ln(E_{\gamma}/E_{\gamma, \text{min}}),$$

(4)

and its standard error $\tau^{\text{max}}$ is given by

$$\sigma(\tau^{\text{max}}) = \sigma(f_{\text{obs}}(E_{\gamma}))/f_{\text{obs}}(E_{\gamma}),$$

(5)

where $\tau(E_{\gamma, \text{min}}, z_e)$ at the lowest energy $E_{\gamma, \text{min}}$ of VHE observations is estimated by the EBL model of Franceschini et al. (2008).

Now we use $\tau^{\text{max}}(E_{\gamma}, z_e)$ to estimate an upper limit on the EBL number density. Following Schroedter (2005) and Finke & Razzaque (2009) we take $d\epsilon/dz = H_0^2$ for TeV sources due to low redshift, where $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$. We assume the monochromatic absorption of VHE photon $E_{\gamma}$ by the EBL at the energy $\epsilon' = 2m_e c^2/(E_{\gamma}(1 + z)) \approx 2m_e c^2/E_{\gamma}$, where the pair-production cross section reaches the highest value, and give an upper limit on the EBL number density, $n(\epsilon, z)$. Using the Dirac delta-function, we write $n(\epsilon, z)$ approximately as

$$n(\epsilon, z) \approx \epsilon' n(\epsilon', z) \delta(\epsilon - \epsilon'). \quad (6)$$

Integrating Eq. (2), we obtain

$$n(\epsilon', z) = \frac{2H_0 \tau^{\text{max}}(E_{\gamma})}{c^2 \pi r_e^2 m_e^2 c^2 \varphi(2)},$$

(7)

where $\varphi(2) = 1.787$. The error of the EBL number density is given by

$$\sigma(n) = \frac{2H_0 c^2 (\tau^{\text{max}}(E_{\gamma}) / c^2 \pi r_e^2 m_e^2 c^2 \varphi(2))},$$

(8)

Finally, the EBL intensity is given by

$$I(\nu, z) = \frac{c^2}{4\pi} \epsilon^2 n(\epsilon, z).$$

(9)

3. Results and discussion

The EBL has two spectral humps with different origins. The blue hump at UV-Optical-NIR (near-infrared) wavelengths comes from stars. The red hump at MIR (mid-infrared) and FIR (far-infrared) wavelengths is from the absorption and re-emission of starlight by the interstellar medium. Therefore, the EBL includes the important information of star formation and evolution.

The TeV blazars used to constrain the EBL are listed in Table 1, where the spectra in the low-flux state are used to the utmost, since the 11-month averaged Fermi spectra are unlikely to correspond to the high state. Through calculation, we find that four blazars, 3C 66A, 0716+714, 3C 279, and PG 1553+113, give stronger constraints on the EBL density. Since other TeV blazars are consistent with all listed EBL models within the error range, we do not give their constraint. The EBL upper limits given by the spectra of four TeV blazars are shown in Fig. 1. The curves of several EBL models are also plotted in Fig. 1: Kneiske et al. (2004), Gilmore et al. (2009), Stecker et al. (2006), Finke et al. (2010), and Franceschini et al. (2008). In this work the calculated limits on the EBL at UV-Optical-NIR wavelengths are strong. For comparison, we also list the lower limits of the EBL from source counts (Madau & Pozzetti 2000). These calculated limits are inconsistent with the fast evolution model given by Stecker et al. (2006) in NIR-Optical wavelengths, but are still compatible with their baseline model. For this fast evolution model, the extinction of UV photons by the interstellar gas in galaxies is not considered, so the UV and Optical-NIR photon density might be overestimated. In fact, the observed gamma-ray hard spectra of H 2356-309 ($z = 0.165$) and 1ES 1101-232 ($z = 0.186$) by Aharonian et al. (2006a) suggest that an upper limit to the EBL at optical-NIR wavelengths is very close to the lower limit given by the integrated light of resolved galaxies. This implies that the EBL is more transparent to high-energy $\gamma$-rays than previously thought, and the contribution from all sources except starlight is less. Essey & Kusenko (2009) suggest a new interpretation of these observations. For distant blazars,
the gamma-ray emission is dominated by the secondary photons, while the emission is from the primary photons for nearby blazars. Therefore, they argue that distant AGN would show no significant attenuation due to pair production on the EBL. In fact, the baseline model gives lower EBL density than the fast-evolution model does, and high EBL density models are disfavored by observations, such as in Aharonian et al. (2006a) and Stecker & Scully (2006). It is shown that they have similar correlations with redshift, but the evolution model does, and high EBL density models are disfavored by observations, such as in Aharonian et al. (2006a) and Stecker & Scully (2006).  

### Table 1. TeV blazar sample.

| Blazar     | Redshift | Fermi photon index (Γ_{Fer}) | VHE photon index (Γ_{VHE}) | E_{min} [TeV] | E_{max} [TeV] | Reference |
|------------|----------|-----------------------------|---------------------------|--------------|--------------|-----------|

Notes. The Fermi data come from Abdo et al. (2010b). VHE data refer to (1) Acciari et al. (2009a); (2) Anderhub et al. (2009); (3) Acciari et al. (2009b); (4) Albert et al. (2007b); (5) Albert et al. (2007c); (6) Albert et al. (2006); (7) Acciari et al. (2009c); (8) Acciari et al. (2008); (9) Albert et al. (2009b); (10) Aharonian et al. (2003); (11) Aharonian et al. (2006b); (12) Albert et al. (2007d); (13) Tagliaferri et al. (2008); (14) Aharonian et al. (2005a); (15) Aharonian et al. (2005b); (16) Albert et al. (2007a); (17) Albert et al. (2007e).
Fig. 2. Difference, \( \Delta \Gamma \), between the measured VHE and Fermi photon indices (or conventional limit 1.5) as a function of the redshift. Red inverted triangles denote the \( \Gamma_{\text{VHE}} - \Gamma_{\text{Fer}} \), and black triangles denote the \( \Gamma_{\text{VHE}} - 1.5 \). The red dash line show the fitting of \( \Gamma_{\text{VHE}} - \Gamma_{\text{Fer}} \).

Georganopoulos et al. (2010). Most of the \( \Gamma_{\text{VHE}} - \Gamma_{\text{Fer}} \) are less than the \( \Gamma_{\text{VHE}} - 1.5 \), and smaller \( \Delta \Gamma \) will provide stronger constraints on the EBL. If using \( \Gamma_{\text{int}} \geq 1.5 \) to limit the EBL is reasonable, \( \Gamma_{\text{int}} \geq \Gamma_{\text{Fer}} \) will be more feasible. 3C 66A and 0716+714 obviously deviate from the correlation shown in Fig. 2, which implies that the assumed redshift might be incorrect.

Since the simultaneous data of Fermi and VHE are less available nowadays, we only use non-simultaneous spectra. We also note that the upper limits of EBL density are depend strongly on the VHE photon index (see Eq. (4)). In fact, no significant spectral variability is observed in VHE bands. For example, \( 3C 66A \) and \( 0716+714 \) appears despite flux variation with a factor of two (Aharonian et al. 2005b, 2008; Albert et al. 2007f, 2009), and its photon index is very similar as observed by HESS and MAGIC (Aharonian et al. 2010a). For PKS 2155-304, no significant spectral variability is observed in VHE bands. For example, 3C 66A and 0716+714 obviously deviate from the correlation shown in Fig. 2, which implies that the assumed redshift might be incorrect.
