ABSTRACT

Aims. We selected two radio quasars (J1036+1326 and J1353+5725) based on their 1.4-GHz radio structure, which is dominated by a bright central core and a pair of weaker and nearly symmetric lobes at $\sim 10''$ angular separation. They are optically identified in the Sloan Digital Sky Survey (SDSS) at spectroscopic redshifts $z > 3$. We investigate the possibility that their core-dominated triple morphology can be a sign of restarted radio activity in these quasars, involving a significant repositioning of the radio jet axis.

Methods. We present the results of high-resolution radio imaging observations of J1036+1326 and J1353+5725, performed with the European Very Long Baseline Interferometry (VLBI) Network (EVN) at 1.6 GHz. These data are supplemented by archive observations from the Very Large Array (VLA). We study the large- and small-scale radio structures and the brightness temperatures, then estimate relativistic beaming parameters.

Results. We show that the central emission region of these two high-redshift, core-dominated triple sources is compact but resolved at $\sim 10$ milli-arcsecond resolution. We find that it is not necessary to invoke large misalignment between the VLBI jet and the large-scale radio structure to explain the observed properties of the sources.

Key words. radio continuum: galaxies – galaxies: active – galaxies: jets – quasars: general – quasars: individual (J1036+1326 – quasars: individual (J1353+5725)

1. Introduction

Active galactic nuclei (AGNs) are believed to be powered by mass accretion onto supermassive (from $\sim 10^6$ up to $\sim 10^{10} M_\odot$) black holes. However, only a small fraction of them (less than 10%) appear luminous at radio frequencies. A typical lifetime of a radio-loud quasar is $\sim 10^9$ yr, so the radio jet activity can be regarded as intermittent in the whole lifetime of an object.

We use the term “restarted activity” for a re-occurrence of radio activity over the lifetime of a source. This can involve interruption and re-ignition of the radio activity (Kaiser et al. 2000), which can be episodic or not. This does not necessarily involve a complete cessation of the radio activity (Schoenmakers et al. 2000b),

The most spectacular examples of recurrent activity in radio-loud AGNs demonstrate rare double-double (e.g. Lara et al. 1999, Schoenmakers et al. 2000a, 2000b, Kaiser et al. 2000) or triple-double (Brockströp et al. 2007) radio galaxies. In these objects, the inner and outer pairs of lobes have a common centre and are generally well aligned (within 8°). The only double-double radio quasar candidate to date, 4C02.27, has been identified by Jamrozy et al. 2009. A recent review of recurrent activity in AGNs, along with a list of known double-double sources has been published by Saikia & Jamrozy 2009. The two highest redshift objects known with confirmed episodic activity are 3C294 ($z = 1.877$) and J1835+6204 ($z = 0.51$) (Saikia & Jamrozy 2009).

A modest fraction of AGNs exhibit triple structures at $\sim 10''$ angular separation with fainter, nearly symmetric extended lobes, and relatively bright compact cores. We call these core-dominated triple sources (CDTs; Marecki et al. 2006). A plausible explanation is that new infalling material from, e.g., a galaxy merger triggers the re-occurrence of accretion. The process could eventually result in the merger of the two highest redshift objects known with confirmed episodic activity.

The National Radio Astronomy Observatory (NRAO) is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc.
Throughout this paper we assume a cosmological model with parameters in the context of possibly restarted activity (Sect. 5). The sources were observed with the European VLBI Network (EVN) at 1.6 GHz. We compared their high-resolution radio images with those obtained from archive VLRA data on the arcsecond scale. In Sect. 2, we describe the selection of the two target sources. In Sects. 3 and 4, we present our observations and describe the radio properties of these compact jets. Here we report on radio-interferometric observations of two high-redshift quasars, J1036+1326 (\(z = 3.10\)) and J1353+5725 (\(z = 3.46\)). We observed these sources with the European VLBI Network (EVN) at 1.6 GHz. We compared their high-resolution radio images with those obtained from archive VLA data on the arcsecond scale. In Sect. 2, we describe the selection of the two target sources. In Sects. 3 and 4, we present our observations and describe the radio properties of the two quasars. Finally, we estimate the viewing angles and analyse the source parameters in the context of possibly restarted activity (Sect. 5). Throughout this paper we assume a cosmological model with \(H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}, \Omega_m=0.3, \) and \(\Omega_L=0.7.\)

2. Target selection

We searched for those compact, high-redshift (\(z > 3\)) radio sources that are unresolved (< 5") in the FIRST survey catalogue\(^2\) (White et al. 1997), that have an integral flux density \(S_{\text{1.4GHz}} > 20 \text{ mJy},\) and that are optically identified with quasars in the Sloan Digital Sky Survey\(^3\) (SDSS). Their spectroscopic redshifts were taken from the 4th edition of the SDSS Quasar Catalog (Schneider et al. 2007) which consists of objects in the SDSS 5th Data Release (DR5). The ultimate goal was to define a sample of radio-loud, optically identified, high-redshift quasars that are good candidates for VLB\(I\) imaging observations. Earlier experience gained from the Deep Extragalactic VLBI-Optical Survey (DEVOS; Mosini et al. 2006) Frey et al. 2008 suggests that the majority (nearly 90%) of the carefully pre-selected compact FIRST-SDSS objects show compact mas-scale radio emission and thus are suitable targets for VLB\(I\) imaging observations at centimetre wavelengths, regardless of spectral index.

We found two peculiar objects (J1036+1326 and J1353+5725) in the sample of ~100 compact high-redshift radio quasars selected using the method above. Although they are catalogued as close pairs of separate, unresolved sources in FIRST, the analysis of archival 1.4-GHz VLA A-array images clearly revealed extended triple structures (see Sect. 3). Both of the bright quasars are associated with weaker two-sided radio lobes; i.e., they satisfy the criteria for CDT sources. We did not apply any selection based on the radio spectrum.

3. Observations and data analysis

3.1. VLA observations

The quasar J1036+1326 was observed with the VLA on 1991 July 8 (project code: AT126). The source J1353+5725 was observed on 1991 June 29 (project code: AR250). For both experiments, the array was in its most extended A configuration, which provided angular resolution of 1”− 1”. The observing frequency was 1.4 GHz. The total on-source integration times were 16 min and 2.5 min for J1036+1326 and J1353+5725, respectively. The data sets were obtained from the NRAO Data Archive\(^4\). For spectral information, we also obtained and analysed archive 8-GHz VLA observations of J1036+1326 (project AR415; 1999 August 9) and 5-GHz VLA observations of J1353+5725 (project AW748; 2008 October 15). The on-source integration time in these two last experiments were 1 min and 9.5 min, respectively. The data calibration was performed using the NRAO Astronomical Image Processing System (AIPS; e.g. Greisen 2003) in a standard way. The 1.4-GHz VLA images of the two sources are shown in Figs. 1 and 2.

3.2. EVN observations

To check whether the VLA cores of J1036+1326 and J1353+5725 are resolved (for example, show a small separation double structure, thus indicating a restarting AGN activity) or unresolved (thus showing evidence of a compact jet) on 10 milli-arcsecond scales, we carried out EVN observations at 1.6 GHz. The 6-hour observations were accommodated in the 2009 September 10-11 e-VLBI run. The data were transferred from the telescopes in real-time to the EVN Data Processor at the Joint Institute for VLBI in Europe (JIVE) in Dwingeloo, the Netherlands (Szomoru 2008). The participating VLB\(I\) stations were Effelsberg (Germany), Jodrell Bank Lovell Telescope, Cambridge (United Kingdom), Medicina (Italy), Toruń (Poland), Onsala (Sweden), Sheshan (P.R. China), and the phased array of the Westerbork Synthesis Radio Telescope (WSRT; The Netherlands). The total aggregate bitrate per station was 512 Mbps. There were eight 8 MHz intermediate frequency channels (IFs) in both left and right circular polarisations.

The sources were observed in phase-reference mode. This allowed us to increase the coherent integration time spent on the target source and thus to improve the sensitivity of the observations. Phase-referencing involves regularly interleaving observations between the target source and a nearby, bright, and compact reference source (e.g. Beasley & Conway 1995). The delay, delay rate, and phase solutions derived for the phase-reference calibrators (J1025+1253 and J1408+5613 in our experiment) were interpolated and applied to the respective target within the target-reference cycle time of 7 min. The target source was observed for 5-min intervals in each cycle. The total accumulated observing time on each target source was 1.6 hours.

The AIPS was used for the VLA data calibration following standard procedures (e.g. Diamond 1995). The visibility amplitudes were calibrated using system temperatures and antenna gains measured at the antennas. Fringe-fitting was performed for the calibrator sources using 3-min solution intervals. The calibrated visibility data were exported to the Caltech Difmap program (Shepherd et al. 1994) where the VLB\(I\) images (Fig. 3) were made after several cycles of CLEAN and phase-only (later amplitude and phase) self-calibration iterations.

D. Cseh et al.: Radio interferometric observations of two core-dominated triple radio sources at $z > 3$

Fig. 1. The naturally-weighted 1.4-GHz VLA A-array image of J1036+1326. The first contours are drawn at $\pm0.25$ mJy/beam. The positive contour levels increase by a factor of 2. The peak brightness is 48 mJy/beam. The Gaussian restoring beam displayed in the lower-left corner is $1''6 \times 1''5$ (full width at half maximum, FWHM) at a major axis position angle PA=17°.

Fig. 2. The naturally-weighted 1.4-GHz VLA A-array image of J1353+5725. The first contours are drawn at $\pm0.6$ mJy/beam. The positive contour levels increase by a factor of 2. The peak brightness is 172 mJy/beam. The Gaussian restoring beam is $1''2 \times 1''0$ at PA=−29°.

Fig. 3. The 1.6-GHz VLBI image of the core of J1036+1326. The first contours are drawn at $\pm0.71$ mJy/beam. The positive contour levels increase by a factor of 2. The peak brightness is 50 mJy/beam. The Gaussian restoring beam is 33 mas $\times$ 6 mas at PA=12°.

Fig. 4. The 1.6-GHz VLBI image of the core of J1353+5725. The first contours are drawn at $\pm1.7$ mJy/beam. The positive contour levels increase by a factor of 2. The peak brightness is 197 mJy/beam. The Gaussian restoring beam is 21 mas $\times$ 4 mas at PA=12°.

4. Results

Observing in phase-reference mode allowed us to determine accurate coordinates of the target sources. For J1036+1326, we obtained right ascension $10^h36^m26^s88565$, declination $+13^\circ26'51''7598$ with an error of 1 mas. For J1353+5725, we obtained $13^h53^m26^s03368$, $+57^\circ25'52''9097$ with an error of 2 mas.

The angular extent of the large-scale 1.4-GHz radio structure of J1036+1326 (Fig. 1) is $15''8$, which corresponds to a projected linear size of $\sim120$ kpc at $z = 3.10$. For the quasar J1353+5725 (Fig. 2), the angular size is $12''23$, and the linear size is $\sim90$ kpc at $z = 3.46$.

$^*$4th edition of the SDSS Quasar Catalog (Schneider et al. 2007)

To place approximate limits on the expansion speed and the viewing angle we used

$$\beta \cos \phi = (R - 1)/(R + 1),$$

(2)

where $\beta = v/c$ is the velocity of the plasma blob ($v$) expressed in the units of the speed of light ($c$), and $\phi$ is the angle between the approaching jet direction and the line of sight eg. (Taylor & Vermeulen 1997).

We can thus derive a lower limit to $\beta$ (because $\cos \phi \leq 1$), and an upper limit to $\phi$ (because $\beta < 1$). For J1036+1326, the constraints ($\phi_1 < 86^\circ$ and $\beta_1 \geq 0.07$) are not very strict, but for J1353+5725 ($\phi_2 < 73^\circ$ $\beta_2 \geq 0.30$) they are more meaningful.

In particular, from the arm-length ratio alone, we can infer that there is mildly relativistic motion in the case of J1353+5725. This method is valid regardless of the specifics of the jet model. It remains valid for the spots or discrete blobs in the head of the jet created by shocks (Schoenmakers et al. 2000) and for pairs of unequally-sized edge-brightened lobes of an FR-II morphology (Fanaroff & Riley 1974).

5.2. Small-scale morphologies and viewing angles

As a starting hypothesis, we assume that the inner radio jets that remain compact with VLB1 (Figs. 3 and 4) are well aligned with the ~100-kpc scale radio structure we see in the VLA images (Figs. 1 and 2). Using the range of the allowed viewing angles ($\phi_1 < 86^\circ$ and $\phi_2 < 73^\circ$) estimated above, we can calculate the Doppler boosting factors ($\delta$) and compare the expected brightness temperatures with our measured values (Table 2, Column 5), in order to determine whether we need to introduce large misalignments to describe the observed morphology.

The observed and intrinsic brightness temperatures are related as

$$\delta = T_b / T_{b,\text{int}}.$$  \hspace{1cm} \text{(3)}$$

where $\delta$ is the Doppler factor. Here we assume a typical intrinsic brightness temperature of $T_{b,\text{int}} \approx 5 \times 10^{10}$ K, which is valid if energy equipartition holds between the magnetic field and the particles in the radio source (Readhead 1994). We obtain Doppler factors $\delta_1 = 0.1$ (which in fact means de-amplification) and $\delta_2 = 2$ for J1036+1326 and J1353+5725, respectively.

The Doppler boosting factor can be expressed as

$$\delta = \frac{1}{\Gamma (1 - \beta \cos \phi)},$$  \hspace{1cm} \text{(4)}$$

where the Lorentz factor is $\Gamma = (1 - \beta^2)^{-1/2}$. For J1036+1326, $\delta_1 = 0.1$, and even the possible maximum value of $\phi_1 = 86^\circ$ can be made consistent if the bulk speed in the inner jet is $v_{\text{bulk}} = 0.9957$. It would correspond to a Lorentz factor $\Gamma \approx 11$, a value often measured in other radio-loud AGNs (e.g. Lister et al. 2009). However, models of the inner jet with much higher Lorentz factors, hence smaller viewing angles, should be considered because of the quasar identification of the source. If we allow for a very high $\Gamma \approx 30$, the misalignment would be ~40°. For comparison, the largest measured misalignment between the inner and outer lobes in 3C293, a double-double radio galaxy, is ~35°, although this is higher than the typical values (Saikia & Jamrozy 2009) and references therein. In our case, the pc-scale structure detected is insufficient for making definitive conclusions about alignment of pc- and kpc-scale structures.

In the case of J1353+5725, the measured Doppler factor ($\delta_2 = 2$) implies a maximum of 30° for the viewing angle because $\sin \phi \leq 1/\delta$ (e.g. Urry & Padovani 1995). Thus we cannot
assume $\phi_i = 72^\circ$ for the inner jet, i.e. we cannot use the same approach as in case of the first source. We can construct a set of reasonable physical and geometric parameters which does not require jet repositioning and is fully consistent with our observations. On the other hand, the largest possible misalignment could reach about $70^\circ$.

In addition, we can set a boundary for the outer $\beta$ parameter by considering the outer structure as an FR-II, since the hot spot advance speeds for high-luminosity FR-II radio galaxies is $\beta \lesssim 0.3$ (e.g. Liu et al. 1992; O'Dea et al. 2009). Even if we use this boundary, we can explain the source without any misalignment; e.g., if the approaching inner and outer jets are both inclined by $\phi = 20^\circ$ to the line of sight, then a bulk jet speed $\beta_{inn} = 0.9903$ would be consistent with the measured Doppler factor in the inner region (Eq. 4). The corresponding Lorentz factor is $\Gamma \approx 7$. On the other hand, $\beta_{out} = 0.31$ and $\phi = 20^\circ$ would be consistent with the observed arm-length ratio (Eq. 2) of the outer structures of J1353+5725 where the jet flow most likely becomes mildly relativistic. Therefore, the observed morphologies do not require invoking the concept of jet repositioning, although our data cannot rule out the possibility of misaligned inner and outer structures.

5.3. The radio spectra

We obtained a two-point radio spectral index of each component in our VLA images (Figs. 1 and 2) and listed in Column 5 of Table 1. In general, the steep spectra of the outer components ($\alpha = -1.2$) may indicate radiative losses. The steep-spectrum sources are good candidates for finding fossils from earlier episodic activity (Sirothia et al. 2009). However, it is not convincing that we see relic lobes in the present case, because, at least for J1036+1326, there is a clear indication of a jet-like feature connecting the core and the northern lobe in the VLA image (Fig. 1). In addition, the core dominance of these sources is somewhat expected at high redshift because the relatively high emitted (rest-frame) frequency is $(1 + z)$ times the observing frequency. Considering the steep spectra of the radio lobes (Table 1), if one places these sources at e.g. $z \approx 0.5$, then the (observed) 1.4-GHz flux density of the brighter lobes in these objects would far exceed that of the flat-spectrum core.

6. Conclusions

We used radio interferometric imaging observations to study the structure of two high-redshift quasars, J1036+1326 ($z = 3.10$) and J1353+5725 ($z = 3.46$). Archive VLA data show that the sources are extended to $\sim 100$ kpc projected linear sizes. They are dominated by a bright central core and a pair of weaker and nearly symmetric lobes. On the other hand, EVN observations at angular resolution that is almost three orders of magnitude higher confirmed that the central jets are compact, at least on $\sim 10$ pc linear scales. CDT sources are sometimes interpreted as examples of once ceased and then restarted radio-loud AGNs. It has been claimed that the reignition of their central engine could be coupled with a change in the spin axis of the central accreting, supermassive black hole, hence with the repositioning of the radio jet direction.

We described a general method for testing the misalignments between the small- and large-scale structures of triple radio sources, using VLA and VLBI imaging observations. We applied this method for two CDT quasars at high redshift ($z > 3$), J1036+1326 and J1353+5725. There is no evidence that their morphology would require any misalignment between their characteristic inner and outer radio structures, although misalignments cannot be ruled out by our data.

Considering the radio spectra of the sources we concluded that the core-dominance of these sources can be explained by their high redshift. The relatively high emitted frequency is $(1 + z)$ times the observing frequency. Taking the steep spectra of the radio lobes into account, if placed to $z = 0.5$, the 1.4-GHz flux density of the brighter lobes in these objects would far exceed that of the flat-spectrum core.

Acknowledgments

The EVN is a joint facility of European, Chinese, South African, and other radio-astronomy institutes funded by their national research councils. This activity is supported by the European Community Framework Programme 7, Advanced Radio Astronomy in Europe, grant agreement no. 227290. The e-VLBI developments in Europe were supported by the EC DG-INFOS funded Communication Network Developments project “EXPReS”, Contract No. 02662. The research leading to these results has received funding from the European Community’s Seventh Framework Programme (FP7/2007-2013) under grant agreement number ITN 215212 “Black Hole Universe”, and the Hungarian Scientific Research Fund (OTKA, grant no. K72515).
