ABSTRACT

Particle acceleration during the magnetorotational instability (MRI) in a collisionless accretion disk was investigated by using a particle-in-cell simulation. We discuss the important role that magnetic reconnection plays not only on the saturation of MRI but also on the relativistic particle generation. The plasma pressure anisotropy of \( p_\perp > p_\parallel \) induced by the action of MRI dynamo leads to rapid growth in magnetic reconnection, resulting in the fast generation of nonthermal particles with a hard power-law spectrum. This efficient particle acceleration mechanism involved in a collisionless accretion disk may be a possible model to explain the origin of high-energy particles observed around massive black holes.

Key words: acceleration of particles – accretion, accretion disks – dynamo – instabilities – magnetic reconnection – plasmas

1. INTRODUCTION

One of the fundamental problems in astrophysics is to understand the outward transport of the angular momentum in an accretion disk in association with the mass accretion inward. The magnetorotational instability (MRI) has been investigated as an efficient mechanism for mass and angular momentum transport (Balbus & Hawley 1991, 1998). It is found that a weakly magnetized disk with outwardly decreasing angular velocity generates magnetohydrodynamic (MHD) turbulence, which can provide angular momentum transport at a greatly enhanced rate. This mechanism is relevant to a large variety of high-energy astrophysical sources where gravitational energy is released through mass accretion.

So far, many simulations in a framework of MHD approximation have been performed to understand quantitatively its angular momentum transport (e.g., Hawley & Balbus 1991, 1992; Matsumoto & Tajima 1995; Stone et al. 1996; Sano et al. 2004). The mean free path of plasma, however, is not necessarily smaller than the characteristic scale length for some classes of astrophysical accretion disks, and the kinetic behavior of MRI beyond the MHD approximation needs to be understood. For example, for an accretion disk around the supermassive black hole at the center of the Galaxy of Sagittarius A* (Sgr A*), the accretion rate is believed to be much less than the Eddington rate, and radiatively inefficient accretion flow models are discussed (e.g., Narayan et al. 1998; Quataert 2003). The accretion proceeds through a hot, low-density, collisionless plasma with a proton temperature higher than the electron temperature, and the equipartition of plasma temperature is not realized during the accretion flow because of a low collision rate. In addition to the nonequilibrium temperature between protons and electrons, nonthermal high-energy particles are observed (e.g., Yuan et al. 2003; Aharonian et al. 2008; Chernyakova et al. 2011; Kusunose & Takahara 2012). It is believed that accretion disks around black holes or supermassive black holes would be important for MRI saturation as well.

In addition to the study of the linear behavior, Sharma et al. (2006) studied the nonlinear evolution of MRI by using their extended MHD simulation model. To incorporate the relaxation process of pressure anisotropy, they utilized the theoretical results of pressure anisotropy instabilities previously studied under homogeneous plasmas (e.g., Gary et al. 1997) and introduced a model equation for the pressure isotropization process. By using the model, they showed that in a collisionless plasma the rate of angular momentum transport can be moderately enhanced during the nonlinear stage.

As their simulation study was based on a fluid model, it was important to investigate the kinetic effects in a fully kinetic approach. Riquelme et al. (2012) performed two-dimensional particle-in-cell (PIC) simulations and confirmed the excitation of the mirror mode and relaxation of pressure anisotropy studied by the previous fluid-based model (Sharma et al. 2006). In addition to the pressure anisotropy effect, the formation of a power-law energy spectrum during magnetic reconnection was pointed out. However, their PIC simulations studied a low plasma \( \beta \) regime of \( \beta = 8\pi p_p/B^2 \) of \( \beta = 0.05–40 \) and used a different boundary condition from the standard open shearing box technique (Hawley et al. 1995).

In this work, we studied the collisionless MRI in a high plasma \( \beta \) regime of \( \beta = 96–6144 \) with the standard open shearing box boundary condition. The pressure anisotropy generated in the course of collisionless MRI is subject to not only the mirror mode and its associated angular momentum transport but also...
the rapid growth of the collisionless magnetic reconnection process. It is known that the reconnection rate is strongly enhanced if the pressure perpendicular to the magnetic field is higher than the parallel pressure. The attention of the reader is drawn to the role of magnetic reconnection with pressure anisotropy, which should lead to the production of significant nonthermal particles and the generation of MHD turbulence during collisionless MRI.

2. PIC SIMULATION IN LOCAL ROTATING FRAME

We focus on the local behavior of the collisionless MRI in the simplest representation of an accretion disk by using a PIC simulation code. Local simulations in the MHD framework have been performed by numerous researchers (Hawley & Balbus 1991, 1992; Matsumoto & Tajima 1995; Stone et al. 1996; Sano et al. 2004), and the generation of MHD turbulence and its angular momentum transport in an accretion disk also have been studied (Balbus & Hawley 1998). The setup of our local kinetic simulation study is basically the same as those investigated in the MHD simulations, but we took into account plasma kinetic effects such as production of nonthermal particles and plasma instabilities caused by pressure anisotropy during the evolution.

As shown by the earlier works (Sharma et al. 2006; Riquelme et al. 2012), the basic behavior of the collisionless MRI is similar to that in an MHD framework, namely, the amplification of a radial magnetic field by the stretching out of a vertical magnetic field and the formation of two inward- and outward-flowing streams. This stretching motion forms the channel flows with both a dense plasma gas and a strong electric current, and then a violent magnetic field energy release process may be expected in the channel flow region by magnetic reconnection. The magnetic reconnection is known to have an important effect on the angular momentum transport in association with the magnetic field amplification, but our motivation in the kinetic simulation was not only to study the angular momentum transport but also to understand how and where the particle acceleration process occurs during MRI under collisionless magnetic reconnection.

2.1. Basic Equations

In our kinetic study of MRI, we performed the PIC simulation in a local frame rotating with angular velocity $\Omega_0$ at a distance $r_0$ from the center. Because the MRI is a class of the local instability, this model was sufficient to capture much of the essential physics. We solved a set of Maxwell’s equations, which include the displacement current $\partial E/\partial t$. Because the local rotating frame with the angular velocity $\Omega_0 = \Omega_0 e_z$ is not an inertial frame, some additional correction terms should be included in a set of Maxwell’s equations (e.g., Schiff 1939). The equations in the local rotating system after the Lorentz transformation can be written by

$$\frac{1}{c} \frac{\partial B}{\partial t} = -\nabla \times E, \quad (1)$$

$$\nabla \cdot B = 0, \quad (2)$$

$$\frac{1}{c} \frac{\partial (E - \frac{v_0}{c} \times B)}{\partial t} = \nabla \times B^* - \frac{4\pi}{c} J, \quad (3)$$

$$\nabla \cdot (E - \frac{v_0}{c} \times B) = 4\pi \rho_c, \quad (4)$$

where $v_0(r) = \Omega_0 e_z \times r$ and

$$B^* = B + \frac{v_0}{c} \times (E - \frac{v_0}{c} \times B). \quad (5)$$

In these equations, we must assume that the distance of the local frame from the center is much less than the light cylinder ($c/\Omega_0$), and we can neglect the terms that have the second order of $v_0/c$ in Equation (5). As a result, we assumed $B^* = B$.

In the same approximation, the equations of motion including Coriolis, centrifugal, and gravity forces are given by

$$\frac{dp}{dt} = e \left( E + \frac{v}{c} \times B \right)$$

$$+ m\gamma \left( 2v \times \Omega_0 - \Omega_0 \times (\Omega_0 \times r) - \frac{GM}{r^2} e_r \right), \quad (6)$$

$$\frac{dx}{dt} = v, \quad (7)$$

where $p = m\gamma v$. The vertical component of gravity is ignored.

We solved the above equations in Cartesian coordinates of $x$, $y$, and $z$, which correspond respectively to the radial direction $x = r - r_0$, the azimuthal direction $y = r_0 \phi$, and the direction parallel to the rotation axis $z$, where the position of $r_0$ is the center of the simulation box. We also assumed that the size of the simulation box ($L'$) was much smaller than its distance to the center of the disk. For a rotating disk around a central object with an angular velocity $\Omega(r)$, the force balance of $GM/r^2 = r\Omega(r)^2$ is satisfied, and we use the tidal expansion of the effective potential with a constant $q = -\partial\ln\Omega/\partial r|_{r_0} \leq r_0$, where the parameter $q$ is set to be $3/2$ for a Keplerian disk. The equation of motion becomes

$$\frac{dp}{dt} = e \left( E + \frac{v}{c} \times B \right) - m\gamma (2\Omega_0 \times v - 2q\Omega_0^2 x e_x). \quad (8)$$

In this work, we studied the time evolution in the meridional plane of $(x, z)$. For simplicity, we set up positron ($e^+$) and electron ($e^-$) plasmas, and save the computational time in PIC code. However, the linear dispersion relations of MRI in pair plasma are the same as in the standard MHD system (see Appendix A).

The above basic equations include the velocity term of $v_0(x, r_0) = \Omega_0(r_0) e_z \times (x + r_0) e_z$, which is a function of the distance $r_0$ from the center, and this term arising from the effect of a noninertial frame appears only as the correction of the displacement current in the Ampère equation and of the electric charge density in the Poisson equation, so that those terms can be, in general, neglected in a low-frequency and long-wavelength MHD regime. In a high-frequency regime, where the amplitude of the electric field is of the same order as that of the magnetic field, i.e., $O(E) \sim O(B)$, the term $v_0 B/c$ is smaller than $E$ if $v_0 \ll c$. For instance, the correction of the noninertial frame term appears as the split of the free-radiation mode. Namely, the phase velocity of the light wave $v_{ph}$ becomes $v_{ph}/c = \pm \sqrt{1 + (k \cdot v_0)^2/(2kc)^2 - (k \cdot v_0)/(2kc)}$, where $k$ is the wave number. We find that the correction is very small as long as $v_0 \ll c$ again. To check the above statement, we performed several simulation runs and compared the results with and without the noninertial frame term, and we found that the results do not change much as long as $L'/2 \leq r_0 < 3L'/2$, where $L'$ is the size of the simulation box. It is not easy to set up the simulation parameter satisfying both $r_0 \gg L'$ and $\Omega_0 r_0 \ll c$.

Table 1

| RUN | A   | B    | C    | D    |
|-----|-----|------|------|------|
| β   | 96  | 384  | 1536 | 6144 |
| (v_{\lambda}/\Omega_0)/R | 50.0 | 35.4 | 25.0 | 17.7 |
| (v_{\lambda}/\Omega_0)/\Delta | 28.2 | 40.0 | 56.5 | 80.0 |
| Ω_{\lambda}/\Omega_0 | 10.0 | 10.0 | 10.0 | 10.0 |
| v_{\pm}/c | 0.0707 | 0.1 | 0.141 | 0.2 |
| V_{\lambda}/c | 1.25 \times 10^{-2} | 8.84 \times 10^{-3} | 6.25 \times 10^{-3} | 4.42 \times 10^{-3} |
| N_\pm | 700 | 600 | 400 | 300 |
| L_\pm | 2.23 | 2.70 | 2.55 | 2.70 |
| N_{p/cell} | 400 | 800 | 1600 | 6400 |

in PIC code because the grid size is limited by the Debye length. As we are interested in the nonlinear evolution of MRI in the MHD frequency range, we may neglect the noninertial frame term with $v_0 \times B/c$ in a set of Maxwell’s equations. In this paper, we have assumed $v_0 = 0$.

2.2. Initial and Boundary Conditions

At the initial condition, a drift Maxwellian velocity distribution function was assumed for both electrons and positrons in the local rotating frame with the angular velocity $\Omega_0(r_0)$. The drift velocity in the y-direction $v_y(x)$ was given by

$$v_y(x) = r \Omega(r) - r \Omega_0(r_0) \equiv \frac{\partial \ln \Omega}{\partial \ln r} \Omega_0(r_0)x = -q \Omega_0(r_0)x,$$

(9)

and other components were $v_x = v_z = 0$.

A nonrelativistic, isotropic plasma pressure with a high plasma $\beta = 8\pi (p_+ + p_-)/B_0^2$ was assumed, where the electron and positron gas pressures were related to the thermal velocities $v_{\pm}$ by $p_{\pm} = (3/2) m_{\pm} n v_{\pm}^2$. The initial magnetic field was set to be purely vertical to the accretion disk, i.e., $B = (0, \ 0, \ B_z)$ in the two-dimensional $x$-$z$ plane. The plasma parameters used in this paper are listed in Table 1. The ratio of cyclotron frequency to the disk angular velocity was fixed to be $\Omega_{\pm}/\Omega_0 = \pm 10$, where $\Omega_{\pm} = \pm \Omega_0 B_0/m_{\pm} c$. The grid size $\Delta$ was set to be $2^{n/2}(v_{\pm}/\Omega_{\pm} p_{\pm} c)$, where $\Omega_{\pm} = \sqrt{8\pi n e^2/m_{\pm} c}$ is the pair-plasma frequency. The Alfven velocity is defined by $V_A = B/\sqrt{8\pi n e^2/m_{\pm} c}$ so that the plasma $\beta$ is equal to $3v_{\pm}^2/V_A^2 N_\pm$ and $N_\pm$ are the grid size of x- and z-directions, and we assumed $N_z = N_r$ in this paper. $L_z = L_x = N_z \Delta / \lambda$ is the physical size normalized by $\lambda = 2\pi V_A \Omega_0$, $N_{p/cell}$ is the number of particles per cell, and a large number of particles are necessary for a high plasma $\beta$ simulation to suppress electrostatic fluctuations.

The uniform magnetic field in space is a simple assumption, the differential rotation velocity $r \Omega_0(r_0)$ is calibrated for the $x$ boundary condition, and the physical quantities at the boundary are obtained by the Lorentz transformation according to the velocity difference of the Keplerian motion between the inner edge and the outer edge. The physical quantities between the inner edge at $x_i = -(L/\lambda)/2$ and the outer edge at $x_o = +(L/\lambda)/2$ can be related by

$$E(x_i, y^*, z) = E(x_o, y, z) + \frac{1}{c} v_\pm \times B(x_o, y, z),$$

(11)

$$B(x_i, y^*, z) = B(x_o, y, z),$$

(12)

$$n_\pm(x_i, y^*, z) = n_\pm(x_o, y, z),$$

(13)

$$J_\pm(x_i, y^*, z) = J_\pm(x_o, y, z) \pm e v_\pm n_\pm(x_o, y, z),$$

(14)

where $y^* = y + q \Omega_0 (L/\lambda) t$ and $v_\pm = q \Omega_0 (L/\lambda) e_\pm$, and we assumed $v_\pm^2/c^2 \ll 1$ and $y_\pm = 1/\sqrt{1 - v_\pm^2/c^2} \sim 1$. The total electric current $J = J_+ + J_-$ can be obtained after the above Lorentz transformation of the pair-plasma densities $n_\pm$ at the boundary. The double periodic boundary condition was used for both y- and z-directions. In our three-dimensional code, we checked that the total magnetic field components were conserved during the time evolution, i.e., $\int_V B dxdydz = const.$

In the previous kinetic simulation reported by Riquelme et al. (2012), they avoided the Lorentz transformation of the electric current at the boundary and implemented shearing coordinates, in which each grid moves with the shearing velocity $v = -q \Omega_0 x$. Our simulation did not use the shearing coordinates and adopted the same boundary condition used in MHD simulations (Hawley et al. 1995).

To solve the kinetic MRI phenomena with better numerical stability, we slightly modified the simulation scheme used in our previous simulation studies. The algorithm is briefly described in Appendix C. Although we have developed a three-dimensional code in the shearing box approximation, in this paper, we only discuss the two-dimensional, meridional evolution of MRI in the $x$-$z$ plane.

3. SIMULATION STUDY OF MRI IN MERIDIONAL PLANE

In this section, we show the time evolution of kinetic MRI by paying special attention to several ingredients such as particle acceleration, magnetic reconnection, and pressure anisotropy. MRI is known to possess a dynamo action by stretching the magnetic field lines under differential rotation motion in a disk, and the antiparallel magnetic field induced by the dynamo action may control the saturation of magnetic field evolution. It is argued that the plasma $\beta = 8\pi p/B^2$ is of the order of $10^{-1}$ in the saturation stage, and the equipartition of energy can be realized (Hawley et al. 1995; Stone et al. 1996; Sano & Inutsuka 2001). During the stage of magnetic reconnection, particle acceleration is highly expected because it is known that the collisionless magnetic reconnection can quickly produce nonthermal particles with energies that exceed the thermal energy (Zenitani & Hoshino 2001, 2005). It is interesting to understand the behavior of particle acceleration during MRI.
3.1. From Linear to Nonlinear Evolution

Figure 1, from top to bottom, shows the time evolution of MRI for $\beta = 1536$ from the initial state to the nonlinear stage. The top four panels are the initial stage with the orbital time of $T_{\text{orbit}} = \tau \Omega_0 / 2\pi = 0.096$, and the other panels from the second row to the fourth row correspond to $T_{\text{orbit}} = 3.39, 4.25,$ and $4.82$. In each row, the pair-plasma density ($n = (n_+ + n_-)/2$ defined by both electron and positron components), the poloidal magnetic field ($B_p = \sqrt{B_x^2 + B_z^2}$), the toroidal magnetic field ($B_t$), and the pair pressure anisotropy ($p_\perp / p_{\parallel}$) defined by the pair components are depicted from left to right. The white lines in the meridional field show the magnetic field lines obtained from the contour of the vector potential of $A_t(x, z)$, and the white arrows superposed in the toroidal magnetic field are the pair-plasma flow vectors $(v_- + v_+)/2$ projected onto the plane. The plasma density and the magnetic fields were normalized by the initial density and the initial total magnetic field, respectively. The $x$ and $z$ coordinates were normalized by $\lambda = 2\pi V_A / \Omega_0$.

At $T_{\text{orbit}} = 0.096$ (first row), the plasmas and magnetic field still remained almost in the initial state, and the structures were uniform in space except for some fluctuations. At $T_{\text{orbit}} = 3.39$ of the linear growth stage (second row), the magnetic field lines are largely folded, and one can see the periodic variation of the poloidal magnetic field intensity in both $x$- and $z$-directions, suggesting that the oblique propagating modes were excited. The magnitude $B_p$ in the intensified region was about five times larger than the initial value. Variations in plasma density, toroidal magnetic field, and pressure anisotropy could also be observed, but the magnitudes of such variations were less than about 10%, suggesting that the unstable mode is basically incompressible and that MRI is mainly provided by the transverse Alfvén/slow mode wave in high $\beta$ plasma. With time, the magnetic field lines were further folded at $T_{\text{orbit}} = 4.25$, and at $T_{\text{orbit}} = 4.82$, a pair of stratified plasma structures associated with...
counterstreaming flows can be observed. The fast flow regions correspond to the high-density current sheet, where the toroidal magnetic field polarity changes. These properties are similar to the standard MRI time evolution in the MHD framework.

One of the important agents in the kinetic MRI mode is the generation of pressure anisotropy (Quataert et al. 2002; Sharma et al. 2003, 2006). We can see the evolution of pressure anisotropy with \( p_\perp > p_\parallel \) (fourth column), where \( p_\perp \) and \( p_\parallel \) are the plasma pressure perpendicular and parallel to the magnetic field, respectively. Roughly speaking, the pressure anisotropy has a good correlation with the total magnetic field. At \( T_{\text{orbit}} = 4.82 \), the strong anisotropy can be clearly seen in the strong magnetic field regions, which correspond to the reddish regions in the poloidal magnetic field and the bluish and reddish regions in the toroidal magnetic field. At \( T_{\text{orbit}} = 4.82 \), the anisotropy reaches \( p_\perp / p_\parallel \sim 3.16 \).

At \( T_{\text{orbit}} = 3.39 \) of the early linear growth stage, the plasma density has a good correlation with the total magnetic field because of the plasma property of the so-called frozen-in condition. At \( T_{\text{orbit}} = 4.25 \), however, the correlation between them is not necessarily good, and at \( T_{\text{orbit}} = 4.82 \), the plasma density has an anticorrelation against the total magnetic field, which may suggest the slow mode wave behavior.

The formation of the strong pressure anisotropy can easily be understood by a double adiabatic equation of state (Chew et al. 1956; Kulsrud 1983), and this behavior has already been discussed in previous kinetic simulations (Sharma et al. 2006; Riquelme et al. 2012). In collisionless plasma, the equation of state describing the evolution of \( p_\parallel \) and \( p_\perp \) can be given by

\[
\frac{D}{Dt} \left( \frac{p_\perp}{\rho B} \right) = 0, \quad (15)
\]

\[
\frac{D}{Dt} \left( \frac{p_\parallel B^2}{\rho^2} \right) = 0, \quad (16)
\]

where the heat flux transport is neglected for simplicity. From the above first equation, which shows the conservation of the first adiabatic motion of the particle, we can understand the enhancement in perpendicular pressure \( p_\perp \) during the time evolution of MRI. The total magnetic field increases during MRI, and the plasma density can also increase by the nature of the frozen-in behavior, but the enhancement in plasma density is relatively small in a high plasma \( \beta \) medium. Then, the perpendicular pressure will have to increase with an increasing total magnetic field. On the other hand, as we can find from the second equation that can be obtained from the first and second adiabatic motions of particles, we know that the parallel pressure decreases slightly with an increasing total magnetic field. In fact, we observed the above behavior in our simulation results. Therefore, it is a natural consequence that the strong pressure anisotropy is induced during the evolution of MRI under the stretching motion of a magnetic field because of the differential rotation of a Keplerian disk, i.e., the MRI dynamo action in association with the folded magnetic field.

Because the pressure anisotropy has free energy in the system, isotropization of plasmas can occur through some plasma instabilities. Under the anisotropy pressure with \( p_\perp / p_\parallel > 1 \) in a high \( \beta \) plasma, the mirror-mode instability and the ion-cyclotron instability may have important effects on the isotropization (Gary & Lee 1994; Gary et al. 1997). As discussed by Sharma et al. (2006), if we use the criteria of the onsets of pitch-angle scattering by the mirror-mode and the ion-cyclotron instabilities of \( p_\perp / p_\parallel - 1 > 7/\beta_\perp \) and \( p_\perp / p_\parallel - 1 > 0.35/\beta_\perp^{0.42} \), respectively, we find that the intersection point of two lines is \( (\beta_\perp, p_\perp / p_\parallel - 1) \sim (187, 0.039) \), and that for a high plasma \( \beta_\perp > \beta_\parallel > 187 \), the onset of the mirror mode occurs faster than the ion-cyclotron instability during the increase in pressure anisotropy.

Because the mirror mode is generated via the instability of the slow MHD wave, the excitation of the mirror mode can be inferred from the anticorrelation between the magnetic pressure and the gas pressure. For instance, at \( T_{\text{orbit}} = 4.82 \), we can see several small spots in the strong anisotropic pressure regions, and we found that the plasma density was high in those regions, whereas the magnitude of the magnetic field and the pressure anisotropy were reduced. The behavior is regarded as the mirror-mode property with the diamagnetic effect.

The size of these spots is of the same order as the gyroradius for the heated plasma under the amplified magnetic field, because the initial gyroradius was 56.6\( \Delta \) = 0.36\( \Delta \), and the local magnetic field is enhanced several tens of times over the initial value at \( T_{\text{orbit}} = 4.82 \). This is also consistent with the kinetic linear theory of the mirror mode (Gary & Lee 1994; Gary et al. 1997). In this way, we observe the excitation of the mirror-mode instability, and the pressure anisotropy can be reduced through the excitation of the mirror-mode wave.

It is interesting to note that the finite pressure anisotropy with \( p_\perp / p_\parallel > 1 \) leads to shifting the unstable mode of the family of MRI to the longer-wavelength region (Sharma et al. 2006). The left-hand panel in Figure 2 shows the linear growth rates of the MRI modes as a function of \( k_z \) and \( p_\perp / p_\parallel \) with the same theoretical framework as studied by Quataert et al. (2002) and Sharma et al. (2006). For a better description of the mirror mode, the heat flux effect is taken into account by using the so-called Landau fluid closure (Hammett et al. 1992; Sharma et al. 2003). The most unstable mode for the case of the isotropic plasma with \( p_\perp / p_\parallel = 1 \) is located around \( kV_A/\Omega_0 \sim 1 \), and the unstable mode shifts toward the smaller \( k_z \) as increasing \( p_\perp / p_\parallel \). If the value of \( p_\perp / p_\parallel \) is slightly smaller than unity, the growth rate is quickly reduced, but the fire-hose instability can be excited in a short-wavelength region.

The dashed curve shows the position of the maximum growth rate obtained from the linear theory in a high plasma \( \beta \) approximation, which can be expressed by

\[
(k_V A)^2 (1 - \beta_\parallel - \beta_\perp / 2) = \frac{15}{16} \Omega_0^2, \quad (17)
\]

For the parallel propagation mode, the effect of pressure anisotropy appears only through the Alfvén speed because there is no coupling between the transverse mode and the compressional/longitudinal wave. The magnetic tension force \( f_{\text{tension}} \) can be modified as \( f_{\text{tension}} = (k_z V_A)^2 (1 - (\beta_\parallel - \beta_\perp) / 2) \), and the Alfvén speed is also modified according to the tension force. On the other hand, the corresponding growth rate can be given by

\[
\Im(\omega) = \frac{3}{4} \Omega_0, \quad (18)
\]

which is the same as in the case of isotropic plasma (Balbus & Hawley 1998).

Let us revisit the simulation result. During the early evolution of MRI, we observed the simultaneous onset of mirror mode and the ionization of pressure anisotropy, but the pressure isotropization was not completed, and some finite pressure anisotropy with \( p_\perp / p_\parallel > 1 \) may remain. In fact, from another
Figure 2. Normalized linear growth rate $\gamma/\Omega_0$ for MRI, mirror, and fire-hose modes for the plasma $\beta = 1536$. The left-hand panel shows the linear growth rate as a function of the wave number $k_z$ parallel to the initial magnetic field (i.e., the rotation axis $\Omega_0$) and pressure anisotropy $p_\perp/p_\parallel$. The perpendicular wave number $k_z = 0$ is assumed. The black dashed lines denote the maximum growth rate for MRI predicted by theory. The fire-hose unstable region appears when $p_\perp/p_\parallel < 1$. The right-hand panel shows the growth rate as a function of $k_z$ and $k_x$ with $p_\perp/p_\parallel = 1.025$. The MRI mode is located in the small parallel wave number region, whereas the unstable mirror mode appears in the large wave number region with the oblique propagation. (A color version of this figure is available in the online journal.)

Figure 3. Time history of Fourier modes for $B_x(k_z)$ propagating parallel to the rotation axis $\Omega_0$. During the early linear growth stage from $T_{\text{orbit}} = 1–2.5$, the mode number $m = 1$ is the fastest growing wave. After $T_{\text{orbit}} > 2.5$, the longer-wavelength mode with $m = 1$ can grow faster. After $T_{\text{orbit}} = 4$, the mode dominates the system and forms the channel flow. (A color version of this figure is available in the online journal.)

analysis, we find that the volume-averaged pressure anisotropy $(p_\perp/p_\parallel)$ is almost isotropic until $T_{\text{orbit}} = 3$, but $(p_\perp/p_\parallel)$ gradually increases up to 1.01 at $T_{\text{orbit}} = 4$, and after $T_{\text{orbit}} = 4$, $(p_\perp/p_\parallel)$ dramatically increases (not shown here). Therefore, it is highly probably that the unstable MRI mode may shift toward a longer-wavelength range during the evolution of pressure anisotropy. Figure 3 shows the time history of Fourier modes of $k_z V_A/\Omega_0 = 0.39, 0.78,$ and 1.18, which correspond to the mode number of $m = 1, 2,$ and 3, where $k_z = (m/N)(2\pi/\Delta)$, where $N$ is the number of the grid point, $\Delta$ is the grid size, and $N\Delta = 2.55(2\pi V_A/\Omega_0)$ in our simulation parameter (see Table 1). Note that the very early stage of $T_{\text{orbit}} = 0–1$ is probably a preinstability stage under the thermal fluctuation, and the evolution of this time interval may depend on the level of the initial thermal fluctuation. After the preinstability stage, one can find that the mode of $m = 2$ grows faster than others until $T_{\text{orbit}} < 2.5$, but after $T_{\text{orbit}} > 2.5$, the mode of $m = 1$ grows rapidly, and eventually the longest-wavelength mode of $m = 1$ dominates the system, which corresponds to the formation of a pair of the channel flows in Figure 1. The linear growth rates $\gamma/\Omega_0$ can be measured from the slopes of the growth curves indicated by the dashed lines in Figure 3, and $\gamma/\Omega_0$ of $m = 1, m = 2,$ and $m = 3$ before $T_{\text{orbit}} < 2.5$ are 0.18, 0.48, and 0.30, respectively. $\gamma/\Omega_0$ of $m = 1$ after $T_{\text{orbit}} > 2.5$ is 0.55. These values are smaller than the theoretical maximum growth rate with $\gamma/\Omega_0 = 0.75$, because the evolution of time-dependent pressure anisotropy may modify the linear behavior.

In addition to the unstable mode shift toward the longer wavelength, the generation of oblique propagating modes is also important in the kinetic MRI evolution. The right-hand panel in Figure 2 shows the linear growth rates as a function of $k_z$ and $k_x$. We fix $p_\perp/p_\parallel = 1.025$. We find that the MRI mode is localized around $k_z V_A/\Omega_0 \sim 1/4$, while the mirror mode appears for obliquely propagating waves with large wave numbers. (Note that this is the fluid-based model, where the growth rate of the mirror mode increases with increasing wave number. The kinetic effects, such as the finite Larmor radius effect, should be taken into account for the understanding of the suppression of the mirror mode in the large wave number regime.) In addition to the MRI and mirror modes, we can see a coupled mode regime connecting to two unstable modes (Quataert et al. 2002; Sharma et al. 2003, 2006).

The oblique mode seen at $T_{\text{orbit}} = 3.39$ in Figure 1 can be interpreted by the coupling of the mirroring and the mirror modes. The simulation does not start from a finite pressure anisotropy, but the pressure anisotropy is generated during the evolution. As the magnitude of the pressure anisotropy is not uniform in space, it is not necessarily good to compare the result of Figure 2 with the simulation result. However, the effect of pressure anisotropy is very strong in a high plasma $\beta$, and we think that the effect should appear even for the early evolution phase of MRI. Sharma et al. (2006) found that the saturation of MRI remains at a very low level if the pitch-angle scattering model is not incorporated in their extended MHD simulation because the pressure anisotropy suppresses the evolution of MRI. Then, Sharma et al. (2006) implemented the pitch-angle scattering model into their simulation and demonstrated that the saturation level that is almost the same as the previous MHD simulation results can be recovered. In our PIC simulation study, the pitch-angle scattering process was included self-consistently, but the ratio of the cyclotron frequency $\Omega_c$ to the rotation frequency $\Omega_0$ was set to be $\Omega_c/\Omega_0 = 10$, which should have a much larger value in a realistic situation. Therefore, the level of the pressure anisotropy discussed in our simulation would be
larger than that expected in a realistic situation. Nevertheless, we observed that the nonlinear evolution of MRI was possible in the self-consistent simulation.

### 3.2. Onset of Magnetic Reconnection under Pressure Anisotropy

As time goes on, the current sheet at the interface of the antiparallel magnetic field in the channel flow becomes thinner, and the onset of magnetic reconnection can be expected in these thin current sheets. Although channel flow is an exact nonlinear solution of MRI without diffusivity, the possibility of the parasitic instability after the stage of channel flow has been discussed by Goodman & Xu (1994). It is interesting to study the nonlinear evolution in a kinetic system, where collisionless/inertia resistivity is self-consistently included.

The nonlinear evolution after the formation of a thin current sheet is shown in Figure 4. The formation of the X-type neutral line was observed at $T_{\text{orbit}} = 5.39$, and the disruption of the current sheet occurred at $T_{\text{orbit}} = 5.48$. For another current sheet situated around $z/\lambda \sim 1.2$, the thinning of the current sheet was observed at $T_{\text{orbit}} = 5.86$, and rapid disruption of the current sheet occurred at $T_{\text{orbit}} = 6.05$. We observed the dynamic evolution of magnetic reconnection associated with the thinning of the current sheet after the formation of the channel flows.

During the formation of the thin current sheet, we observed the amplified magnetic field and the strong pressure anisotropy outside the channel flow/current sheet, and the peak value of $p_\perp/p_\parallel$ reached 18.7 at $T_{\text{orbit}} = 5.39$. A pileup of the poloidal magnetic field just outside the current sheet, as indicated by the reddish color region, can also be observed, not only outside the current sheet but also inside the current sheet. We can observe the pressure anisotropy of $p_\perp > p_\parallel$. The pressure anisotropy is particularly important for the onset of reconnection (e.g., Chen & Palmadesso 1984; Hoshino 1987). The averaged pressure anisotropy and density integrated along the $x$-direction, namely, $\int p_\perp(x, z)dx / \int p_\parallel(x, z)dx$ and $\int \rho(x, z)dx/(L_x \lambda)$, are shown in Figure 5. Panels (a) and (b) are at $T_{\text{orbit}} = 5.39$ and at $T_{\text{orbit}} = 5.48$, respectively. In panel (a), we can clearly see $p_\perp/p_\parallel > 1.3$ for the central current sheet just before the onset of reconnection, and $p_\perp/p_\parallel \sim 1$ for the upper current sheet. At $T_{\text{orbit}} = 5.48$, after the break of the central current sheet but before the onset of reconnection for the upper current sheet, we can find that $p_\perp/p_\parallel > 1.2 \sim 1.4$, while the pressure anisotropy is significantly reduced for the central current sheet. Panel (c) is the result for the lower plasma $\beta = 96$. As in the case of the

![Figure 4](image-url)
The pressure anisotropy still increasing. The MRI process is still very active at this time stage through the release of magnetic field energy and pressure isotropization inside the islands. The reduction in pressure anisotropy $p_{\perp}/p_{\parallel}$ can be understood with the same argument based on the double adiabatic theory described by Equations (15) and (16). Since the reconnecting magnetic field leads to magnetic field dissipation in the high-density region of the current sheet, the collisionless magnetic reconnection has a tendency to form pressure anisotropy with $p_{\parallel}/p_{\perp} > 1$ in the reconnecting current sheet (e.g., Higashimori & Hoshino 2012). In fact, we observe $p_{\perp}/p_{\parallel} \sim 0.3$–0.4 in the region surrounded by magnetic islands at $T_{\text{orbit}} = 6.05$.

After the break in the current sheet and the formation of magnetic islands, the latter islands are still subject to further MRI time evolution. The magnetic island situated in the center, which corresponds to the central current sheet in Figure 4, is stretched in the radial direction of $x$. This kind of evolution can also be seen in the late evolution as shown in Figure 6. The island situated in the lower current sheet can be further extended in the radial direction and forms an elongated current sheet structure at $T_{\text{orbit}} = 6.62$. This time evolution of the elongating island is basically the same as that discussed by Hawley & Balbus (1991). The elongated current sheet becomes unstable and is reconnected at $T_{\text{orbit}} = 6.62$–6.81, and at $T_{\text{orbit}} = 6.81$, the island/current sheet is strongly deformed and is being spread over the entire region of the simulation box. The toroidal magnetic field and pressure anisotropy are also reduced during this stage. At the almost-final stage of our simulation of $T_{\text{orbit}} = 7.95$, we observed a further amplified poloidal magnetic field $B_{\text{poloidal}}/B_0 \sim 330$, while the toroidal magnetic field was reduced to $B_{\text{toroidal}}/B_0 \sim 50$. We could see the well-shaped magnetic island and the spread plasma gas surrounding the island. We have performed several other simulation runs with different simulation box sizes and various plasma parameters, and we obtained the result that the final stage was either two magnetic islands or a single island surrounded by the distributed plasma gas.

3.3. Particle Acceleration during Magnetic Reconnection

Figure 7 shows the history of the energy spectra during MRI, which were taken at $T_{\text{orbit}} = 0.09, 5.39$–6.81, and 7.95. The horizontal and vertical axes are the total energy $e/mc^2$ and the number density $N(e)$, respectively. At $T_{\text{orbit}} = 5.39$, just before the onset of reconnection, the energy spectrum still had a Maxwellian-like distribution. After the onset of reconnection at $T_{\text{orbit}} = 5.48$, nonthermal particles with a large flux were generated, while the thermal plasma pressure did not change much. During the time interval between $T_{\text{orbit}} = 5.86$ and 6.05, further production of nonthermal particles was observed.

So far, the particle acceleration during magnetic reconnection has been discussed in numerous works. Zenitani & Hoshino (2001) argued that the relativistic effect of the Speiser motion around the X-type region can form a power-law energy spectrum by drifting along the reconnection electric field because the higher energetic particles can resonate preferentially with the reconnection electric field because of the relativistic inertia effect. Another important agent of acceleration is that the acceleration efficiency can be improved for an elongated current sheet because the charged particle by the Speiser motion can remain in the acceleration region for a longer time. As the result
of both effects, the accelerated power-law energy spectrum can become harder (Hoshino & Lyubarsky 2012). The other important effect of the reconnection acceleration is the pressure anisotropy. As discussed in the previous subsection, the pressure anisotropy of $p_{\perp} > p_{\parallel}$ enhances the growth rate of reconnection by coupling to the mirror mode, and it seems likely that the stronger induced electric field significantly contributes to the nonthermal particle production.

During the repeated process of disruption and formation of the current sheet, the plasma gas could be heated and the nonthermal particles could be accelerated, and the energy spectrum became harder and harder. Additionally, the nonthermal energy density increased compared with the thermal energy density. In the almost-final stage of this simulation run at $T_{\text{orbit}} = 7.95$, the energy spectrum could be approximated by $N(\varepsilon)d\varepsilon \propto \varepsilon^{-1}$. The maximum energy was reached at $\varepsilon/mc^2 \sim 10^2$, for which the gyroradius of the highest energetic particle was almost equal to the size of the simulation box. We will discuss this point later by compiling other simulation results.

4. PLASMA $\beta$ DEPENDENCE

So far, we have discussed the case with $\beta = 1536$ and have found that the pressure anisotropy plays a key role in
Figure 8. Time evolution of MRI for plasma $\beta = 96$. The format is the same as in Figure 1. At the linear growth stage at $T_{\text{orbit}} = 3.80$, both the MRI mode propagating parallel to the rotation axis $z$ and the obliquely propagating mirror mode can be clearly seen in the poloidal magnetic field. However, the growth of the mirror mode is relatively weak in the low plasma $\beta$ regime, and two channel flows (i.e., four current sheets) are formed at $T_{\text{orbit}} = 5.16$. The evolution of the late nonlinear stage after the onset of magnetic reconnection is basically the same as the higher plasma $\beta$ cases.

(A color version of this figure is available in the online journal.)

4.1. MRI Evolution for $\beta = 96$

Figure 8 shows the time evolution for the plasma $\beta = 96$ in the same format as Figure 1. At the linear growth stage of $T_{\text{orbit}} = 3.80$, both the MRI mode propagating parallel to the rotation axis $z$ and the obliquely propagating mirror mode can be clearly seen in the poloidal magnetic field. However, the growth of the mirror mode was relatively weak during the nonlinear evolution in the low plasma $\beta$ regime, and two channel flows (i.e., four current sheets) formed at $T_{\text{orbit}} = 5.16$. As the size of the simulation box was $2.28 \times (2\pi V_A/\Omega_0)$, the observed unstable mode number $m = 2$ was roughly consistent with the linear theory with isotropic pressure. In contrast to the case with $\beta = 1536$ in Figure 1, we did not observe a shift in wavelength toward the longer-wavelength mode during the linear growth phase.

In fact, we could confirm the weak effect of pressure anisotropy for the low plasma $\beta$ case in the linear analysis of Figure 9. The format is the same as in Figure 2. The same topology of the vertical magnetic field relative to the accretion disk was assumed. The qualitative behavior of the instability was the same as in the case of plasma $\beta = 1536$ in Figure 2, but the growth rate became less sensitive to pressure anisotropy. From the left-hand panel showing the relationship between the parallel wave number $k_z$ and pressure anisotropy $p_{\perp}/p_{\parallel}$, the shift in wavelength because of pressure anisotropy appeared for a relatively larger anisotropy, as suggested by the linear theory of $(k_z V_A)^2(1 - (\beta_{\parallel} - \beta_{\perp})/2) = (15/16)\Omega_0^2$. To get fire-hose instability, a larger pressure anisotropy with $p_{\perp}/p_{\parallel} < 0.98$ is required as well. The right-hand panel shows the coupling of the mirror mode and MRI for $p_{\perp}/p_{\parallel} = 1.025$. We found that the linear growth rates for the obliquely propagating mirror mode were small compared with the high plasma $\beta = 1536$ case. This weak coupling to the mirror mode was consistent with the simulation result.

Let us look again at the simulation result in Figure 8. The snapshot at $T_{\text{orbit}} = 5.43$ shows the formation of magnetic
islands, and the interaction of several magnetic islands that were formed from the four current sheets could be seen at $T_{\text{orbit}} = 5.16$. However, the dynamic evolution of the nonlinear stage was basically the same as for the high plasma $\beta$ case, and the almost-final stage at $T_{\text{orbit}} = 8.15$ had two magnetic islands. One of the islands contained a strong magnetic field and high plasma density, whereas the other had a weak magnetic field and low plasma density. These two magnetic islands had opposite polarities of the electric current $J_y$, and further magnetic reconnection could not occur for the two islands.

Let us discuss the pressure anisotropy in the current sheet before the onset of reconnection for the low plasma $\beta = 96$. The averaged pressure anisotropy at $T_{\text{orbit}} = 5.16$ is shown in panel (c) of Figure 5. We observe $p_\perp / p_\parallel > 1.3$, a value that is almost the same as the higher plasma $\beta = 1536$ case. We also checked the pressure anisotropy inside the current sheets for two other runs, B and D with $\beta = 384$ and 6144, and found the same behavior of $p_\perp / p_\parallel \sim 1.3$ before the onset of reconnection. We conclude that the pressure anisotropy produced during MRI played a significant role in the onset and rapid growth of reconnection.

### 4.2. Total Magnetic Field, $\alpha$ Parameter, and Energy Spectra

Let us study the amplification of the magnetic field and $\alpha$ parameter during MRI. So far, many MHD simulation studies have reported that the magnetic field is amplified during the exponential growth of the MRI within several rotation periods (e.g., Balbus & Hawley 1998; Sano et al. 2004; Sharma et al. 2006) and that the plasma $\beta = 8\pi p_0 / B^2$ in the saturation stage is of the order of 0.01–1, where $p_0$ is defined as the initial gas pressure (e.g., Hawley et al. 1995). We note that in the open shearing box simulation, the gas pressure continued to increase throughout the evolution by gaining gravitational potential energy.

Figure 10 shows the time history of the total magnetic field energy and the total plasma pressure/kinetic energy integrated in the entire simulation domain. The horizontal and vertical axes denote the orbital time and the normalized energies of magnetic field (solid line) and plasma pressure/kinetic energy (dashed line), respectively. The rapid increase in magnetic field energy and plasma pressure occurs almost with the same timing for the lower plasma $\beta = 96$ and 384, but for the higher plasma

![Figure 10](https://example.com/figure10.png)

Figure 10. Time history of the total kinetic energy (dashed line) and magnetic field energy (solid line) for four different plasma $\beta$ cases with $\beta = 96$, 384, 1536, and 6144. The energies are normalized by the initial magnetic field energy.
\( \beta = 1536 \) and 6144, the gradual increase in magnetic field energy appears earlier than the rapid increase in plasma pressure. The stages of the gradual increase in magnetic field correspond to the formation of the obliquely propagating mirror mode. The timing of the rapid growth of both the magnetic field energy and plasma pressures corresponds to the beginning of the formation of the channel flow for all plasma \( \beta \).

After the onset of the energy increase, energy equipartition can be realized in the nonlinear phase between the magnetic and the kinetic energies. However, as discussed in the previous sections, after the onset of magnetic reconnection and the subsequent repeated processes of formation and deformation/disruption of the current sheet, the magnetic field energy is quickly released, and the plasmas are gradually heated. In the end of the simulation, we found that the plasma \( \beta = 8 \pi p_0/B^2 \) was of the order of 0.01–1, which coincides with earlier MHD simulation experiments. The plasma \( \beta = 8 \pi p/B^2 \) defined by using the instantaneous pressure becomes several tens regardless of the amplitude of the initial magnetic field. It is interesting to note that the amplification of the total magnetic field energy was about \( 10^4 \) times the initial state for all our simulations, but this result might depend on the simulation box size, because the size of the final magnetic island probably depends on the box size.

Let us study the angular momentum transport in our two-dimensional simulations by numerically measuring the stress tensor given by

\[
\tau_{xy} = \rho v_x (v_y + q \Omega_0 x) - \frac{B_x B_y}{4\pi} + \left( \frac{p_\parallel - p_\perp}{B^2} \right) B_x B_y.
\]

Each of the terms on the right-hand side represents the Reynolds \( (\tau_{xy}) \), Maxwell \( (\tau_{xz}) \), and anisotropy \( (\tau_{yz}) \) stresses, respectively (Sharma et al. 2006). As the above stress tensor is related to the energy dissipation rate in the system, the so-called \( \alpha \) parameter in the standard accretion disk model (Shakura & Sunyaev 1973) can be defined by

\[
\alpha = \frac{\tau_{xy}}{p} = \frac{w_R + w_M + w_A}{p},
\]

where \( p \) is the plasma pressure. We measured the \( \alpha \) parameters during the active reconnection stage and during the almost-final stage with a relatively quiet phase. For instance, the “active” reconnection stage corresponds to the time interval of \( T_\text{orbit} = 6–7.5 \), whereas the almost-final, “quiescent” stage is \( T_\text{orbit} = 7.5–9 \) for the case with \( \beta = 96 \). Namely, we defined the active reconnection phase by the time interval during which the magnetic energy is greater than that in the almost-final stage. We found that \( w_M > w_R > w_P \) during the active phase, and \( w_M > w_p > w_P \) during the almost-final phase in our simulation results. Figure 11 shows the measured \( \alpha \) parameters for four different plasma \( \beta \). The diamond and square symbols stand for the “active” phase and the “quiescent” final phase, respectively. We found that \( \alpha \sim 10^{-1–10} \) during the active phase, while \( \alpha \) was about \( 10^{-3–10^{-2}} \) during the almost-final stage. Roughly speaking, these values seem to support the standard \( \alpha \) disk model (Shakura & Sunyaev 1973).

Finally, we examined the energy spectrum and the maximum attainable energy. The energy spectra obtained from the almost-final stages of four plasma \( \beta \) RUNs with \( \beta = 96, 384, 1536, \) and 6144 are shown in Figure 12. Regardless of plasma \( \beta \), the well-developed nonthermal spectra can be formed during MRI, and the high-energy tail can be approximated by a power-law spectrum of \( N(\varepsilon) \varepsilon^{-1} \). The maximum attainable energies are probably limited by the gyroradius of the simulation box size, and the maximum energy \( \varepsilon_{\text{max}} \) can be expressed by

\[
\varepsilon_{\text{max}} \sim \frac{e B_f}{mc^2} \left( \frac{L_x}{\lambda} \right) \sim \left( \frac{V_A}{c} \right) \left( \frac{\Omega_e}{\Omega_0} \right) \left( \frac{B_f}{B_i} \right) \left( 2\pi L_x \right),
\]

where \( B_f/B_i \) is the ratio of the magnetic field amplification and \( L_x \) is the normalized simulation box size normalized by \( \lambda = 2\pi V_A/\Omega_0 \). As we can see in Figure 10, the ratio of \( B_f/B_i \) is about \( 10^2 \) regardless of plasma \( \beta \). Referring to the plasma parameters of \( V_A/c, \Omega_e/\Omega_0, \) and \( L_x \) listed in Table 1, we can obtain the maximum attainable energy \( \varepsilon_{\text{max}}/mc^2 \sim 174, 150, 100, \) and 75 for the corresponding \( \beta = 96, 384, 1536, \) and 6144, respectively. The high-energy cutoffs in Figure 12 seem to be consistent with the above simple discussion.

5. DISCUSSION AND SUMMARY

We discussed the nonlinear time evolution of MRI in a collisionless accretion disk, where the mean free path is longer than the typical scale size of the disk. We found that the collisionless MRI can produce significant amounts of nonthermal particles during the saturation stage through magnetic reconnection. The pressure anisotropy of \( p_\parallel/p_\perp > 1 \) initiated during the nonlinear evolution of MRI can lead to a rapid onset of magnetic reconnection by coupling of the tearing and mirror modes (Chen &
Palmadesso 1984), and its strong inductive electric field excited by the fast reconnection can enhance the efficiency of particle acceleration.

In our simulation experiments, we used a relatively small simulation box, but it is supposed that many magnetic islands may form in a large accretion disk system and that further nonthermal acceleration may occur. As one of the possible acceleration processes in many magnetic islands, the stochastic “Fermi-reconnection acceleration” has been discussed recently by Hoshino (2012). In the standard Fermi acceleration model (Fermi 1949), charged particles gain energy stochastically during head-on and head–tail collisions of particles with magnetic clouds as the scattering objects, and the increase in particle energy is known to be the second order of \( V_c / c \), where \( V_c \) and \( c \) are the velocity of the random motion of the magnetic clouds and the speed of light, respectively. On the other hand, Hoshino (2012) proposed the stochastic Fermi-reconnection acceleration by introducing the interaction of charge particles with many magnetic islands instead of the magnetic clouds, and discussed that the acceleration efficiency becomes first order of \( V_A / c \).

To check the possibility of the stochastic Fermi-reconnection acceleration, we examined the relationship between the thermal plasma density and the energetic particle density in the system. Figure 13 shows the color contours of the densities of the thermal plasma (left) and the energetic particles (right). The white lines show the magnetic field lines. (A color version of this figure is available in the online journal.)

Figure 13. Color contours of the densities of the thermal plasma (left) and the energetic particles (right). The white lines show the magnetic field lines.

We observed the repeated processes of current sheet formation by stretching the magnetic field and the deformation/disruption of a current sheet by reconnection, and during the repeated processes with the active reconnection, strong turbulence was observed. However, after several repeated processes, the fluctuation levels were reducing with time, and we obtained a more or less “quiescent” state, where the plasma flow fluctuations were relatively weak. We discuss the two-dimensional behavior of MRI in the collisionless system in this paper, but needless to say, the study of a three-dimensional simulation is needed. In general, the plasma transport processes may be different between two- and three-dimensional systems, and the saturation of MRI and the angular momentum transport studied in this paper would be modified in three-dimensional MRI. We will discuss three-dimensional evolution of MRI in another paper.

Our simulation study has several limitations, but a couple of important implications may be given for interpreting the observed high-energy particle emission from massive black holes such as Sgr A* (e.g., Narayan et al. 1998; Quataert 2003; Yuan et al. 2003; Aharonian et al. 2008; Chernyakova et al. 2011; Kusunose & Takahara 2012). Magnetic reconnection involved in a collisionless accretion disk can be regarded as a plausible process to generate not only high-energy particles but also MHD turbulence because a small but finite pressure anisotropy of \( p_\perp > p_\parallel \) induced by MRI plays an important role in the onset and growth of reconnection. By virtue of the active reconnection caused by the coupling between the tearing and mirror modes,
a strong inductive reconnection electric field enhances the particle acceleration efficiency, and the angular transport may be enhanced during the active reconnection phase through strong turbulence as well. The collisionless reconnection with \( p_\perp > p_\parallel \) might lead to an efficient mass accretion to maintain a collisionless accretion disk.

This work was supported in part by JSPS Grant-in-Aid for Scientific Research (KAKENHI) grant No. 25287151. The author thanks R. Matsumoto, T. Sano, S.-I. Inutsuka, K. Hirabayashi, and K. Shirakawa for valuable discussions.

APPENDIX A
LINEAR DISPERSION FOR MRI IN PAIR PLASMAS

We perform a linear analysis of MRI in pair plasmas and show that the basic property of MRI instability in a pair plasma is the same as that discussed in a one-fluid MHD system. A set of the basic property of MRI instability in a pair plasma is the

\[
\frac{\partial n_{\pm}}{\partial t} = -\nabla \cdot (n_{\pm} v_{\pm}), \tag{A1}
\]

\[
(\frac{\partial}{\partial t} + v_{\pm} \cdot \nabla) v_{\pm} = -\frac{1}{n_{\pm} m_{\pm}} \nabla p_\pm + \frac{e_{\pm}}{m_{\pm}} (E + \frac{v_{\pm}}{c} \times B) - 2\Omega_0 v_{\pm} + 2q\Omega_0 x e_x, \tag{A2}
\]

\[
\frac{\partial B}{\partial t} = -\nabla \times E, \tag{A3}
\]

\[
\nabla \times B = \frac{4\pi}{c} (e_+ n_+ v_+ - |e_-| n_- v_-), \tag{A4}
\]

\[
\frac{D}{Dt} \left( \frac{p_{\pm}}{n_{\pm}} \right) = 0. \tag{A5}
\]

We assume that the initial magnetic field has only a \( z \) component, i.e., \( B_0 = (0, 0, B_0) \), gas pressure \( p_{\pm} \) is constant, and the initial Keplerian velocity shear has a \( y \) component, i.e., \( v_0_{\pm} = (0, -q\Omega_0 x, 0) \), where \( q = -\partial \ln \Omega / \partial \ln r = 3/2 \). With this assumption, the electric field should satisfy the condition of \( E = -v_{0, \pm} \times B_0/c \). Because of this finite electric field, however, the initial number density of \( n_{\pm} \) is not exactly the same, but the charge difference of \( (n_+ - n_-)/n_+ \sim O((V_A^2/c^2)(\Omega_0/\Omega_e)) \ll 1 \) is neglected in this analysis.

In the linearized equations, we also assume the charge neutrality with \( \delta n_+ = \delta n_- \). We define the sum and difference of the perturbed fluid velocities for the positron and electron as

\[
\delta u \equiv (\delta v_+ + \delta v_-)/2, \tag{A6}
\]

\[
\delta w \equiv (\delta v_+ - \delta v_-)/2. \tag{A7}
\]

By this definition, the sum and difference of the momentum equation yield

\[
-i\omega \delta u - \Omega_0 q \delta v_+ e_y = \delta w \times \Omega_0 e_z - 2\Omega_0 \delta e_z \times \delta w + \frac{e}{m} \delta E + \Omega_0 v_0 e_y \times \delta B/B_0, \tag{A9}
\]

and the Ampère’s Equation (A4) can be written as

\[
\delta w(\Omega_0/V^2_A) = i k \times \delta B/B_0. \tag{A10}
\]

To eliminate \( \delta E \), we substitute Equation (A9) into Faraday’s Equation (A3) and use Equations (A8) and (A10). Assuming the linear perturbation form of \( \exp(i(k \cdot x - i\omega t)) \) with the wave vector \( k = (k_x, 0, k_z) \), we finally obtain the dispersion relation as

\[
(\omega^2(1 + \varepsilon) - k^2_+ V^2_A(1 - (q - 2)^2 v)) 
\times \left( (1 + \varepsilon)\frac{\omega^2 - k^2 V^2_A}{\omega^2 - k^2_+ V^2_A} - k^2 V^2_A + \Omega_0^2(2 - q)\varepsilon \right) 
= \Omega_0^2(2 - q)(2(1 + \varepsilon) + \varepsilon(2 - q)) 
\times \left( \omega^2(1 + \varepsilon) + \frac{q}{2 - q} k^2 V^2_A 
+ k^2 V^2_A \left( (q - 2) + \frac{\omega^2}{\omega^2 - k^2 V^2_A} v \right) \right). \tag{A11}
\]

where \( \varepsilon = k^2 V^2_A/\Omega^2_0, \varepsilon = \Omega^2_0/\Omega^2_e, \) and \( k = \sqrt{k^2_x + k^2_z} \). In the limit of both \( \varepsilon \to 0 \) and \( v \to 0 \), the above dispersion relation can be simplified as

\[
(\omega^2 - k^2 V^2_A) \left( \omega^2 - \frac{k^2 V^2_A}{k^2_+ V^2_A} - k^2 V^2_A \right) 
= 2\Omega^2_0(2 - q) \left( \omega^2 + \frac{q}{2 - q} k^2 V^2_A \right). \tag{A12}
\]

The first term on the left-hand side shows the shear Alfvén mode, and the second term represents the slow and fast modes, whereas the right-hand side is the coupling term caused by the differential rotation. This dispersion equation is exactly the same as that obtained in the MHD system. Therefore, the linear MRI behavior in a pair plasma should be same as that in a one-fluid MHD equation.

APPENDIX B
AN EQUILIBRIUM SOLUTION FOR THE VERTICAL MAGNETIC FIELD GEOMETRY

For our kinetic MRI study in the meridional plane, the initial magnetic field \( B_0 \) is orthogonal to the Kepler velocity \( v_0 \), and then a finite motional electric field \( E_0 \) appears, which varies in the radial direction. Therefore, a finite electric charge density \( \rho_e \) may appear as well. The order of magnitude of the charge density is

\[
\frac{\rho_e}{en_{\pm}} \sim \frac{1}{cen_{\pm}} \nabla \cdot (v_y \times B_0) \sim \frac{V^2_A}{c^2} \Omega_0. \tag{B1}
\]

where \( V^2_A = B^2/4\pi nm \) and \( \Omega_e = eB/mc \), and we can easily find that this charge separation is very small in the low-frequency MHD regime.

To obtain a better initial condition including charge separation, however, we solve the coupled Ampère’s and Poisson’s
equations as follows:

\[
4\pi \rho_e(x) = \nabla \cdot \left( E(x) - \frac{v_0}{c} \times B(x) \right)
= -\frac{1}{c} \nabla \cdot ((v_y(x) + v_0(x))e_y \times B_z(x)e_z),
\]

(B2)

\[
v_y(x)\rho_e(x) = J(x) = \frac{c}{4\pi} \nabla \times (B_z(x)e_z),
\]

(B3)

where \( v_y(x) = -q\Omega_0 x \) with \( q = 3/2 \) for a Keplerian disk and \( v_0(x) = \Omega_0(x + r_0) \) is the term arising from the noninertial frame. By eliminating the charge density, we obtain

\[
\frac{1}{B_z(x)} \frac{\partial B_z(x)}{\partial x} = \frac{\alpha x}{1 + \beta x - \alpha x^2},
\]

(B4)

where \( \alpha = \Omega_0^2 q(q - 1)/c^2 \) and \( \beta = \Omega_0^2 q r_0/c^2 \). This differential equation can be solved analytically, but by assuming \( \alpha \ll \beta \ll 1 \), we have the solution as

\[
B_z(x) = \frac{B_0}{\sqrt{1 + \beta x - \alpha x^2}},
\]

(B5)

Furthermore, if we neglect the noninertial term of \( v_0(x) \), the solution becomes

\[
B_z(x) = B_0/\sqrt{1 - \alpha' x^2},
\]

(B6)

where \( \alpha' = (q\Omega_0/c)^2 \). We basically used this form as the initial condition in our simulations. Note that the simulation domain is much less than the light cylinder \( c/\Omega_0 \), and then \( \alpha' x^2 \ll 1 \).

Next, let us obtain the corresponding distribution of the finite charge density \( \rho_e(x) \). We have assumed the same number density between positrons and electrons, i.e., \( n_e(x) = n_{-}(x) = n(x) \), but a different charge density is adopted between electrons and positrons, i.e., \( e_+ \neq |e_-| \) by keeping \( m_+ / m_- = e_+/|e_-| \) in our simulation. By using Equations (B3) and (B6), the corresponding charge density correction can be obtained by

\[
\frac{\rho_e(x)}{e_n n_0} = \left( \frac{e_+ - |e_-|}{e_+} \right) \frac{n(x)}{n_0} = \frac{B_0 q \Omega_0}{4\pi e_n n_0 c} \frac{1}{(1 - \alpha' x^2)^{3/2}},
\]

(B7)

and we adopt the solutions of

\[
\frac{e_+ - |e_-|}{e_+} = \frac{B_0 q \Omega_0}{4\pi e_n n_0 c}
\]

and

\[
\frac{n(x)}{n_0} = \frac{1}{(1 - \alpha' x^2)^{3/2}}.
\]

In addition to these corrections of magnetic field and charge density, the plasma gas pressure is adjusted to satisfy the pressure balance of

\[
\frac{B_z^2(x)}{8\pi} + \frac{n(x)(T_e(x) + T_-(x))}{m_e} = \text{const}.
\]

(B10)

In our equilibrium solution, plasma pressure is also a function of \( x \). This solution is an equilibrium solution in the level of fluid approximation, but it would not be necessarily a Vlasov equilibrium. We used \( V_A / c \sim 10^{-2} - 10^{-3} \) and \( \Omega_0/\Omega_A = 10^{-1} \) in this paper, so that these correction terms are of the order of \( 10^{-5} \). Therefore, no significant difference may appear for the nonlinear evolution with or without the correction terms.

**APPENDIX C**

**SIMULATION CODE**

We briefly describe our simulation code, which was slightly modified from the STARFIELD code (Hoshino 1987; Hoshino et al. 1992). The velocities and positions of particles were integrated in time by using the standard Buneman–Boris methods, namely,

\[
\frac{p^{n+1/2} - p^{n-1/2}}{\Delta t} = e \left( E_{\text{mod}}^n + \frac{v^{n+1/2} + v^{n-1/2}}{2c} \times B_{\text{mod}}^n \right),
\]

(C1)

\[
x^{n+1} - x^n \Delta t = v^{n+1/2},
\]

(C2)

where \( \rho = \gamma m v \) and a suffix \( n \) shows a time step. The modified \( E_{\text{mod}}^n \) and \( B_{\text{mod}}^n \) terms by the Coriolis and tidal forces are given by

\[
E_{\text{mod}}^n = E^n + \frac{2m}{e} \gamma \Omega_0 x e_z,
\]

(C3)

\[
B_{\text{mod}}^n = B^n + \frac{2m}{e} \gamma \Omega_0 x e_z.
\]

(C4)

After the calculation of motion of equations, we could obtain the electric current \( J^{n+1/2} \) by using

\[
J^{n+1/2} = \sum_{\text{particle}} e v^{n+1/2} S(x^{n+1/2}),
\]

(C5)

where \( S(x) \) is the so-called shape function providing a way the particle density and velocity are distributed into the grid around its center.

The semi-implicit time integration with the finite-difference method in space was used to advance a set of Maxwell’s equations. Our scheme is described by

\[
\frac{1}{c} \left( \frac{E^{n+1}_{\text{mod}} - E^n}{\Delta t} - \frac{v_0}{c} \times \frac{B^{n+1}_{\text{mod}} - B^n}{\Delta t} \right)
= \nabla \times (a B^{n+1}_{\text{mod}} + (1 - a) B^{n}) - \frac{4\pi}{c} J^{n+1/2},
\]

(C6)

\[
\frac{1}{c} \left( \frac{B^{n+1}_{\text{mod}} - B^n}{\Delta t} \right)
= -\nabla \times (a E^{n+1}_{\text{mod}} + (1 - a) E^{n}),
\]

(C7)

where \( v_0 = \Omega_0 \times r \) is the term of a noninertial frame rotating with the angular velocity \( \Omega_0 \). \( \nabla \times \) is replaced by either the finite-difference equation in space or \( i k \times \) in Fourier space. The semi-implicit parameters of \( a \) and \( \alpha \) can control the numerical stability. If \( a = 1/2 \) and \( \alpha = 1 \), the time integration becomes basically the centered difference approximation in time. On the other hand, the semi-implicit parameters of \( \alpha > 0.5 \) and \( a < 1 \) can make the time integration numerically stable.

To solve the above Maxwell’s equations in the finite-difference approximation in space, the electric field \( E^{n+1/2} \) is removed from Equations (C6) and (C7), and we first solve the
second-order differential equation for $\mathbf{B}_{n+a}$ by the conjugate gradient method. Then we obtain $E_{n+a}$ from Equation (C6). Another method is to use Fourier transformation where the so-called numerical dispersion error is free, but this may present a disadvantage in massive parallel computing.

For proceeding to the next time step, we need the information of velocity $v_{n+a-1/2}$ and position $x_{n+a}$, which are obtained by the interpolation of

$$v_{n+a-1/2} = av_{n+1/2} + (1 - a)v_{n-1/2},$$  \hspace{1cm} (C8)$$

$$x_{n+a} = ax_{n+1} + (1 - a)x_{n}. \hspace{1cm} (C9)$$

In this method, all physical quantities are advanced in time with the time step of $\Delta t$, where $a$ is the same value used in the set of Maxwell’s equations. By using $a < 1$, we can numerically suppress both the high-frequency and the large wave number electromagnetic and electrostatic waves. In our MRI simulation, we used $a = 0.98–1.0$.

In the moment calculation of $\mathbf{J}$, we used the standard charge conservation method proposed by Villasenor & Buneman (1992). This method, in general, does not require solving the Poisson equation, but our open shearing box boundary condition may lead to small but nonnegligible numerical inconsistency between the electrostatic field calculated by Equation (3) and the Poisson equation of Equation (4), because the motion of particles across the boundary and the electric and magnetic fields at the boundary are interpolated to match the open shearing box condition. Therefore, to calculate the electrostatic field at the boundary correctly, we also solve the Poisson equation at every time step given by

$$\nabla \cdot \left( E_{n+a} - \frac{\mathbf{v}_0}{c} \times \mathbf{B}_{n+a} \right) = 4\pi \rho^n_{\text{tot}}. \hspace{1cm} (C10)$$

The correction of the electric field is useful for suppressing electrostatic waves excited by numerical errors around the boundary.
