Early metazoan cell type diversity and the evolution of multicellular gene regulation

Arnau Sebé-Pedrós, Elad Chomsky, Kevin Pang, David Lara-Astiaso, Federico Gaiti, Zohar Mukamel, Ido Amit, Andreas Hejnol, Bernard M. Degnan and Amos Tanay

A hallmark of metazoan evolution is the emergence of genomic mechanisms that implement cell-type-specific functions. However, the evolution of metazoan cell types and their underlying gene regulatory programmes remains largely uncharacterized. Here, we use whole-organism single-cell RNA sequencing to map cell-type-specific transcription in Porifera (sponges), Ctenophora (comb jellies) and Placozoa species. We describe the repertoires of cell types in these non-bilaterian animals, uncovering diverse instances of previously unknown molecular signatures, such as multiple types of peptidergic cells in Placozoa. Analysis of the regulatory programmes of these cell types reveals variable levels of complexity. In placozoans and poriferans, sequence motifs in the promoters are predictive of cell-type-specific programmes. By contrast, the generation of a higher diversity of cell types in ctenophores is associated with lower specificity of promoter sequences and the existence of distal regulatory elements. Our findings demonstrate that metazoan cell types can be defined by networks of transcription factors and proximal promoters, and indicate that further genome regulatory complexity may be required for more diverse cell type repertoires.

The origin of animal multicellularity has been linked to the spatial coexistence of cell types with distinct roles. Cell type specialization is achieved through asymmetric access to genomic information, which is interpreted in a cell-specific fashion through mechanisms of transcriptional gene regulation. However, it remains unclear how elaborate genome regulation relates to cell type diversity. Poorly characterized, early-branching metazoans represent an opportunity to explore these questions by studying how cell-type-specific genome regulation is implemented in species with (presumed) intermediate-to-low organismal complexity. Phylogenetically, sponges, comb jellies and placozoans—together with the remaining metazoans (Planuloza)—are the earliest-branching animal lineages (Fig. 1). These organisms possess characteristic body plans and have been traditionally considered to contain low numbers of cell types, although our current understanding of this diversity of cell behaviours remains very limited. Moreover, these three lineages diverged over 650 million years ago (Ma), which has resulted in extremely different and specialized morphologies, life strategies and body plan organization. Ctenophores are mostly pelagic, marine predators. They have tissue-level organization and they develop a nervous system of uncertain homology with their bilaterian counterparts. By contrast, sponges are sessile filter-feeders that live both in marine and freshwater environments and that seem to have no or very rudimentary specialized tissues. Finally, placozoans are tiny benthic marine animals with a body plan organization that is composed of two cell layers. They possess ciliary-based locomotion and feed on algae using external digestion. Sponges, ctenophores and placozoans also vary considerably in their overall genome size, median intergenic space and repertoire of potential transcriptional and post-transcriptional regulators (Fig. 1). The genome of the sponge Amphimedon queenslandica measures 166 megabases (Mb), and its annotation suggests a relatively compact gene arrangement with very short (0.6-kilobase (kb)) intergenic regions. In comparison, the protozoan species Trichoplax adhaerens, a smaller genome (98 Mb) but longer intergenic regions (2.7 kb) are reported. Annotation and comparison of the predicted proteome in these non-bilaterian species uncovered an extensive suite of gene families shared across Metazoa, suggesting the existence of ancient regulatory mechanisms for orchestrating cell type specification and maintenance. For example, sponge, ctenophore and placozoan genomes encode large repertoires of transcription factors and chromatin modifiers and remodelers, representing intermediate diversity compared with unicellular species and other metazoans (for example, cnidarians or bilaterians) (Fig. 1). However, comparative analysis of genomic regulatory programmes in non-model organisms is confounded by the scarcity of direct molecular data on cell states and genome regulation. Whole-organism single-cell RNA sequencing (RNA-seq) opens an opportunity to start closing this gap, by performing extensive sampling of transcriptional programmes and characterizing cell type repertoires in diverse metazoan lineages. Here, we generate transcriptional maps at single-cell resolution for Amphimedon queenslandica, Trichoplax adhaerens, and Mnemiopsis leidyi. These maps, in combination with chromatin data and sequence analysis, allow us to survey the cell type diversity and compare the genomic regulatory programmes in these non-bilaterian animal lineages.

Results
An atlas of Amphimedon queenslandica adult and larval cell types. To study sponge cell type diversity, we collected adult and larval specimens...
from *A. queenslandica*. We processed fresh cells using the massively parallel single-cell RNA-seq (MARS-seq) protocol with small adaptations\(^2\) (see Methods), profiling a total of 4,992 adult and 3,840 larval *A. queenslandica* cells (Supplementary Fig. 1 and Supplementary Table 1). Whole-organism single-cell analysis involves processing cells with highly heterogeneous RNA content, given the expected differences in size and/or transcriptional activity between distinct cell types (Supplementary Fig. 1a,b). To maximize the sensitivity of our assay, we retained for subsequent analysis all sampled cells with at least 100 unique molecule identifiers (UMI). Applying the MetaCell framework (Supplementary Appendix 1), we found over 300 marker genes in each stage, which showed a high degree of intrapopulation transcriptional variance (Supplementary Fig. 1c). Using this approach, even cells with overall low UMI counts were characterized by a sufficient number of marker genes (Supplementary Fig. 1d). This allowed us to robustly group 81–94% of our single cells into transcriptionally coherent clusters, which we call metacells (Supplementary Fig. 1e,f; see also Methods and Supplementary Appendix 1), and to apply a bootstrap approach to support these metacells (Supplementary Fig. 1g; see also Methods). Moreover, we associated each of the derived metacells with a set of differentially expressed genes (Supplementary Tables 2 and 3) and used the functional annotation of these gene sets to annotate at least some of the metacells.

The power of whole-organism single-cell RNA-seq analysis to characterize cell types is demonstrated by visualizing *A. queenslandica* adult metacells (Fig. 2a), key marker genes in two-dimensional (2D) projection (Fig. 1b) and a heat map showing the distribution of marker genes at single-cell resolution (Fig. 2c). The sponge transcriptional landscape is dominated by large groups of choanocytes, pinacocytes and archaeocytes\(^1\). Even though these groups can be further subdivided into subclasses, their annotation into broad types is supported by common transcriptional signatures of key genes. Choanocytes are autonomous filter-feeding cells with a unique morphology, characterized by a flagellum surrounded by a microvilli collar\(^3\). Our data show that *A. queenslandica* choanocytes express RNA-binding proteins such as *mbl*, *bruno2* and *nanos*, as well as multiple proteins of the flagellar apparatus, and annexins\(^4\) (Fig. 2b and Supplementary Fig. 2b,h). They also specifically express multiple adhesion proteins, including cadherins and C-type lectins (Fig. 2b). Interestingly, not only choanocytes, but also other cell types we identified express unique combinations of adhesion proteins; for example, distinct integrin alpha/beta paralogue pairs (Supplementary Fig. 2a). These cell-type-specific adhesion molecules, especially those like cadherins and immunoglobulins that mediate homophilic interactions, are likely to be important in the spatial sorting of cell types and general sponge body plan organization. Finally, based on their expression, we can define two broad types of choanocytes (Fig. 2a) showing differences not only in their repertoire of effector genes but also in the expression of transcription factors.

Another abundant group of cells are pinacocytes (Fig. 2a,c). Pinacocytes are epidermal cells that cover the outer and inner surfaces of the sponge\(^5\). Our data show that *A. queenslandica* pinacocytes specifically express *pumilio* RNA-binding protein and multiple components of the actin contractility apparatus, including *tropomyosin*, *calponin* and *striated-type myosin II* (Fig. 2b and Supplementary Fig. 2a). This suggests that *A. queenslandica* pinacoderm has some contractile properties, as also indicated by experiments in the demosponge *Tethya wilhelma*\(^6\). Interestingly, we also identify a cluster of cells that show intermediate transcriptional profiles between choanocytes and pinacocytes, expressing both choanocyte markers, such as *fgf* and *bruno2* and pinacocyte marker proteins such as *FGF, Bruno2* and *Calponin* (Fig. 2a).

Gene identifiers from ref. 17. The 2D cell projection is the same as in a. c, Normalized gene expression across 4,803 *M. leidyi* single cells (columns), sorted by metacell. Metacell numbers are indicated. For each cluster, the top 25 genes sorted by fold change versus the other metacells were selected for visualization (with a fold-change threshold of ≥2). d, 2D projection of *T. adhaerens* metacells and single cells. Gene expression distribution on 2D projected *T. adhaerens* cells for selected gene markers. Gene identifiers from ref. 18. The 2D cell projection is the same as in d. e, Normalized gene expression across 3,209 *T. adhaerens* single cells (columns), sorted by metacell. Metacell numbers are indicated. Genes were selected as in c. The colour-coding of cells and metacells in a and d is arbitrary.

markers, such as *pumilio* (Fig. 2b). In addition, these cells specifically express *hedging* (Fig. 2b), a cadherin with an amino-terminal hedgehog domain.26,27. These data suggest the existence of transcriptional states representing trans-differentiation intermediates between cell types, a process known to occur in multiple sponge species, including *A. queenslandica*.28,29.
Another major sponge cell behaviour identified here corresponds to archaeocytes, which are pluripotent amoeboid cells found in the sponge mesohyl (the gelatinous matrix that fills the sponge body)\(^29\). We find that these cells express specific extracellular matrix proteins such as, fibrinogen\(^2\), granulins and large amounts of diverse RNA-binding proteins such as, magonashi\(^1\) (Fig. 2b and Supplementary Fig. 2b,c). The extensive usage of cell-type-specific RNA-binding proteins observed chiefly in archaeocytes, but also in other sponge cell types (Fig. 2b and Supplementary Fig. 2b), is in line with previous reports that suggest a pervasive role of this type of regulators in another sponge species, *Ephydatia fluviatilis*\(^2\). In addition to these abundant cell types, we detect in adult *A. queenslandica* remarkably distinct, yet much less abundant, cell types. These include sperm cells, defined by expression of *tpvr* ion channel, *tseg* and other genes associated with sperm function (Fig. 2b and Supplementary Fig. 2d), as well as collagen-producing cells (Fig. 1b), cells expressing multiple *aspezcinc* protease paralogues (Fig. 2b and Supplementary Fig. 2e) and host defence cells producing antibacterial proteins (Supplementary Fig. 2f).

Unlike the other species included in this study, but similar to many marine invertebrates\(^1\), *A. queenslandica* has a biphasic life cycle involving two dramatically different post-embryonic stages: adult and larva\(^2\). We therefore profiled single-cell transcriptomes in the lecitotrophic larva of *A. queenslandica* to identify larval cell types and compare them with those found in adult sponges. We sampled the transcriptomes of 3,840 larval single cells and identified metacells with specific expression signatures using the same strategy described for the adult (Fig. 2d,e and Supplementary Table 2). This analysis revealed at least seven different cell types in the larva (Fig. 2d,e). Based on published expression patterns for marker genes, we could identify some of these cell types. These include ciliated epithelial cells that express ciliary markers (Fig. 2e), flusk cells\(^3\), *wnt*-expressing posterior pole cells\(^4\) and *tgb* expressing anterior pole cells\(^4\). When comparing transcriptional signatures, larval cell types show remarkable differences compared with adult cell types: 4.8% of the genes expressed in the larva (689/14,426) are not expressed in the adult and, reciprocally, 39.9% (9,010/22,567) of adult genes are not expressed in the larva. Direct metacell comparisons (Fig. 2g) show that, in fact, only one larval cell type shows strong similarity with an adult cell type: archaeocytes. Overall, this indicates that the *A. queenslandica* larval stage deploys a unique set of cell types, as also the case when compared with the adult sponge. This is known to also be a ciliary regulator in bilaterians\(^76\).
behaviours with no counterparts in the cell types that emerge after the larva metamorphoses into an adult. M. leidy cell type diversity. Ctenophores were traditionally considered to be a sister group to cnidarians. However, recent phylogenomics studies clearly show they are one of the earliest-branched animal lineages, although it remains disputed whether they branched before or after sponges (Fig. 1). Ctenophores have a complex body plan and cell types such as muscles and neurons. These features, together with the ctenophore phylogenetic position, open the question of whether neurons and other cell types have single or multiple origins within Metazoa. We mapped the diversity of cell types in the ctenophore M. leidy by profiling 6,144 single-cell transcriptomes. Compared with the sponge, mapping of the ctenophore M. leidy transcriptional states uncovered a richer repertoire of cell types, some of which could be associated with putative functions and known cell types (Fig. 3 and Supplementary Table 4). For example, we identified a group of photocyte cells (the cells responsible for ctenophore bioluminescence) expressing known photoproteins and opsins (Fig. 3b). Unlike most other metazoans, ctenophore locomotion is based on the coordinated ciliary beating of rows of comb cells. We identified comb cells expressing multiple ciliary markers and specific potas
dium voltage-gated and amiloride-sensitive sodium ion channels (Fig. 3e and Supplementary Fig. 3). Comb cells also express a specific innexin gene (Fig. 3e), supporting the existence of gap junctions electrically coupling these groups of cells, as suggested by ultrastructural observations. Another group of cells show expression of markers associated with muscle cell types in other species, such as tropomyosin and calponin (Fig. 3e and Supplementary Fig. 3). In contrast, although M. leidy lacks striated muscles, we can distinguish a group of muscle cells expressing markers associated with striated muscles in other species, such as striated-type myosin II, while another group of muscle cells express markers of ‘smooth’ muscles, such as calponin (Fig. 3b and Supplementary Fig. 3a). We also detect cells showing expression of digestive enzymes and genes associated with the formation of microvilli and filopodia (such as diapha
nous and cortactin) (Fig. 3b), a group of cells expressing a secreted Shk-domain protein (Fig. 3b), and epithelial cells expressing multiple transmembrane adhesion and extracellular matrix proteins (Supplementary Fig. 3b).

However, most of the cell clusters we identified cannot be assigned to known functions/types and many are strongly associated with unannotated proteins (Supplementary Table 3), often Ctenophora
-specific (see Fig. 4e). This emphasizes our still very limited understanding of ctenophore biology. Interestingly, we could not identify any metacell with distinct neuronal gene expression signatures such as those observed in cnidarians and bilaterians. For example, different synaptic scaffold components are expressed across multiple cell types and no specific cell cluster shows co-expression of multiple voltage-gated ion channels. This lack of co-expression is similar to that observed for synaptic scaffold and other neuronal genes in A. queenslandica and T. adhaerens (see below)—two organisms without neuronal cells. Instead, we find in M. leidy highly specific expression in multiple metacells of electrical synapse components (innexins), as well as specific expression of ASC, iGLuR and K/Ca/Na ion channels (Fig. 3b and Supplementary Fig. 3c–h). Overall, these findings indicate a dramatically different molecular composition of ctenophore synapses and neuronal-like cells from those of cnidarians and bilaterians, possibly suggesting convergence of these cell types and their expressed genes in two ciliated epithelial layers and the flattened body is filled with extracellular matrix material and fibre cells. We dissociated and sampled the transcriptomes of 4,608 T. adhaerens cells (Fig. 3d–f, Supplementary Fig. 4 and Supplementary Table 5) and defined metacells and putative cell types using the same strategy as for A. queenslandica and M. leidy. In line with the known biology and ultrastructure of T. adhaerens, we defined groups of fibre cells, lipophil cells, digestive and gland cells, and epithelial cells, comprising in total 79% of the sampled cells. Fibre cells express markers associated with cell contractility, such as tropomyosin and calponin (Fig. 3e and Supplementary Fig. 4g), as well as cell adhesion and extracellular matrix proteins such as integrins, collagens and fibro
nectins (Fig. 3e and Supplementary Fig. 4c–g). This suggests a dual role of these cells in generating the extracellular material that fills the body of T. adhaerens, as well as enabling the body contraction involved, for example, in placozoan feeding behaviour. Lipophil cells express multiple lysosome and lipid metabolism genes (Fig. 3e and Supplementary Fig. 4d), gland cells express different digestive enzymes such as trypsinps (Fig. 3e and Supplementary Fig. 4h), and epithelial cells express multiple defensins—short peptides involved in host defence (Fig. 3e and Supplementary Fig. 4e). Both gland and epithelial cells express ciliary markers (Fig. 3e and Supplementary Fig. 4f), as expected given that they are both ciliated cell types.

Besides these four abundant cell behaviours, our analysis reveals seven additional lower-frequency cell types, six of which are characterized by the production of unique regulatory peptides and multiple specific transcription factors (Figs. 3c,5f). One of these regulatory peptides (TaelP, Fig. 3e) has recently been shown to regulate T. adhaerens locomotion through control of ciliary beating of the cells in the lower epithelial layer. Therefore, we hypothesize that the five other peptidergic cell types uncovered in this study may be involved in the control of additional processes, such as the release of digestive enzymes from gland cells or the contraction of fibre cells. However, although the T. adhaerens genome encodes multiple genes involved in synaptic and neuronal functions, these genes do not show co-expression in these peptidergic cell types (Supplementary Fig. 4b), indicating the absence of a synaptic scaffold or any other neuronal gene module. Overall, the observed states indicate that elaborated peptidic regulation occurs in this simple animal within specialized cell types that lack the characteristics of synaptic neurons.

Phylogenetic patterns of cell-type-specific gene repertoires. To study the evolutionary dynamics of these cell-type-specific transcriptional programmes, we used phylogenetic mapping to define gene ages and orthology relationships in A. queenslandica, M. leidy and T. adhaerens (Supplementary Table 6). First, we analysed the possible cross-species conservation of cell-type-specific expression correlation over orthologous gene pairs. This showed that, at the evolutionary distances separating these three species from their common ancestor (>635 Ma), co-regulation of genes is almost completely divergent (Fig. 4a–c). In fact, we only observed conserved co-regulation of specific housekeeping functions, including ribosomal proteins and flagellar apparatus.

Next, we analysed how gene age correlates with cell type transcriptional specificity (Fig. 4d–k). We defined for each gene in each species an inferred evolutionary origin based on the presence of orthologues in species belonging to key taxonomic groups and A. queenslandica-specific genes (24%). In T. adhaerens, panneur
karyotic genes are even more dominant, representing over 50% of all expressed genes, and a similar percentage of the genes that are expressed in a cell-specific manner; while there is only a modest
Fig. 5 | Transcription factor regulatory programmes in A. queenslandica, M. leidyi and T. adhaerens. a, Number of transcription factors encoded in the genome, detected in our single-cell RNA-seq analysis and showing cell-type-specific expression in each species. b, Number of transcription factors belonging to different structural classes detected in A. queenslandica (left), M. leidyi (middle) and T. adhaerens (right). c, Cell type specificity of transcription factors compared with all genes for each species. Cell-type specificity of each gene was measured as the maximum fold-change enrichment of its expression in any metacell. The midline indicates the median, the box ranges from the first to third quantile, the whiskers are the 1.5 times the interquartile range. **P<0.0001 (Wilcoxon rank-sum test). d, Heat map (centre) showing A. queenslandica correlation between transcription factors based on expression profiles across metacells. Only transcription factors with >20 total molecules and a fold change of >1.8 in at least one metacell are included. On both sides, bar plots show the expression profile across metacells for representative transcription factors in each transcription factor module. Asterisks indicate the position of the transcription factors shown in bar plots in the heat map (in the same descending order). e, f, Same as d, but for M. leidyi (e) and T. adhaerens (f).
Fig. 6 | Regulatory sequence analysis in A. queenslandica, M. leidyi and T. adhaerens. a, De novo motif enrichments in A. queenslandica promoters. Left: heat map showing significant (FDR < 0.02) motif (rows) enrichments in the promoters of metacell-specific gene sets (columns). Right: heat map showing the similarity of each A. queenslandica promoter-enriched motif (rows) to known motifs in databases (columns). The coloured bar indicates whether the motif has high similarity (> 0.7) with any known motifs and/or de novo motifs found in the other two species. b, c, Same as a, but for M. leidyi (b) and T. adhaerens (c). d, Boxplots showing, for each species, the frequency of occurrence of metacell-specific motifs in the promoters of metacell-specific genes compared with all other genes promoters (left) and compared with the whole genome (right). **P < 0.0001, *P < 0.05, NS, not significant (Wilcoxon rank-sum test). e, Boxplot showing, for each species, the distribution of de novo motif entropies. **P < 0.0001, *P < 0.05 (Wilcoxon rank-sum test). f, Scatterplots for A. queenslandica (left), M. leidyi (middle) and T. adhaerens (right), showing the maximum similarity of each de novo motif to known motifs (x axis) and motifs in the other two species (y axis). The highlighted cases (top) show examples of motifs that are highly similar between two species and not similar to any known motif in databases. g, Left: correlation between observed (obs.) and predicted (pred.) expression values derived from a linear model based on promoter motif content analysis for the T. adhaerens metacell 42 (peptidergic cells). Correlation is shown as a function of the total molecule count threshold applied to the genes considered in the analysis. The three motifs with the top coefficients according to the model are shown. Right: receiver operating characteristic curve of the linear regression model predicting gene expression in metacell 42 (peptidergic cells). h, Same as g, but for A. queenslandica metacell 32 (archaeocytes). i, Pie charts for M. leidyi (left) and T. adhaerens (right) showing the distribution of H3K4me2 peaks across different genomic features, grouped by overlap or lack of overlap with H3K4me3 peaks. H3K4me3 + K4me2 peaks in non-promoter regions are likely to represent unannotated promoter sites. Numbers indicate the percentage for each category. j, iChIP signal metaplots centred in promoter peak maximum coverage positions for H3K4me3 (left) and H3K4me2 (right) and in T. adhaerens (top) and M. leidyi (bottom). iChIP signal is indicated as -log(1 - coverage quantile), see Methods. k, Fraction of H3K4me2/3 peaks observed in promoter regions in M. leidyi (left) and T. adhaerens (right). **P < 0.0001, NS, not significant (χ² test). l, Example T. adhaerens (top) and M. leidyi (bottom) genomic regions showing normalized H3K4me2 and H3K4me3 iChIP coverage. m, M. leidyi H3K4me2/3 iChIP signal metaplots centred at enhancer element maximum H3K4me3 positions. n, De novo motif enriched in M. leidyi enhancers. The bar plot shows the frequency of occurrence of this motif in M. leidyi enhancers and promoters.
contribution of genes specific to *T. adherens* (17%) in the cell-type-specific transcriptomes. By contrast with *A. queenslandica* and *T. adherens*, in the ctenophore *M. leidyi*, most cell-type-specific genes are of ctenophore origin (40%). This suggests an important contribution of ctenophore gene innovations to ctenophore cell type biology and also explains the difficulty of determining the identity of many of the cell clusters we identified in this species (Fig. 3a–c).

In general, genes that are expressed broadly across tissues have been shown to have older phylogenetic origins, while genes expressed in a narrower subset of tissues tend to have more recent phylogenetic origins. To test whether the same effect is observed in cell type transcriptomes, we defined for each gene a cell type specificity score (based on the maximum fold change in expression observed in any metacell) and stratified these values according to gene age (Fig. 4f,g). In all three species, we observed that evolutionarily more novel genes show a significantly higher degree of cell-type-specific regulation. At a higher resolution, specific cell clusters show distinct gene-age distributions (Fig. 4i–k). For example, sponge choanocytes are particularly enriched in genes specific to the sponge lineage, whereas, archaeocytes and sperm cells are enriched in panekaryotic genes (Fig. 4i). In the ctenophore, digestive cells are enriched in genes of holozoan origin (that is, shared between animals and their closest unicellular relatives), while epithelial cells and multiple uncharacterized cell types are enriched in ctenophore genes (Fig. 4j). A similar pattern is observed in the placozoan *T. adherens*, with epithelial cells being enriched in lineage-specific genes, while lipopolys are enriched in panekaryotic genes and digestive cells are enriched in genes shared between placozoans, cnidarian and bilaterians (ParaHoxozoa) (Fig. 4k).

Cell-type-specific transcription factor modules. Transcription factors are key players in the gene regulatory networks that define cell type identity. We examined transcription factor cell-type-specific expression to test whether the observed cell type transcriptional programmes are linked to a rich transcription factor repertoire. We detected expression for 168, 231 and 129 predicted transcription factors in *A. queenslandica*, *M. leidyi* and *T. adherens*, respectively (Fig. 5a and Supplementary Fig. 5a). The classification of predicted transcription factors into structural classes suggested expanded usage of homeobox and zf-C2H2 transcription factors in the ctenophore, but otherwise similar representation of transcription factor classes between these species (Fig. 5b). Consistent with their probable role as key drivers of cell type regulation, we found that transcription factors are much more likely to be expressed in a cell-type-specific fashion compared with all other genes (Fig. 5c). Accordingly, we found different transcription factors being specifically expressed in all cell types in each of the species. In *A. queenslandica*, we observed *maf*, *grainyhead* and 27 other transcription factors enriched in choanocytes; *ets* and *ark* homeobox are specific to pinacocytes; and Mycmyc is expressed in archaeocytes (Fig. 5d and Supplementary Fig. 5b,c). Less frequent sponge cell types also show highly specific transcription factor expression. For example, sperm cells show co-expression of four *tbx6/7* paralogues, and host defence cells express *interferon regulatory* factor (Fig. 5d and Supplementary Fig. 5b,c). In *M. leidyi*, *grainyhead* transcription factor is enriched in epithelial cells and *rfx3* is enriched in the ciliated comb cells (Fig. 5e and Supplementary Fig. 6a). These transcription factors have been shown in other species to be expressed in epithelial cells and ciliated cells, respectively, suggesting conserved association of these transcription factors with epithelial and ciliary programmes. Examples of cell-type-specific transcription factor regulators in *T. adherens* include *noto* homeobox in lophophor cells and *foxC* in fibre cells (Fig. 5f and Supplementary Fig. 6b). Interestingly, while an overall similar number of transcription factors are expressed in a cell-type-specific fashion across the three species (Fig. 2a), in the ctenophore, the higher cell type complexity results in a smaller number of transcription factors linked to each transcriptional state, suggesting that additional epigenetic mechanisms might be involved in cell type specification for this species; for example, genomic compartmentalization and combinatorial gene regulation by distal regulatory elements. In summary, elaborated combinatorial expression of transcription factors is observed to correlate—and possibly drive—differentiated transcriptional programmes in sponges, ctenophores and placozoans.

Genomic embedding of cell type regulatory programmes in early metazoans. Transcription factors regulate their target genes by binding to sequence elements located at promoters and, most prominently in bilaterians, at distal enhancers. To reconstruct the degree to which information encoded into gene promoters can direct cell-type-specific transcriptional control in early metazoans, we defined sets of cell-type-specific gene modules for each species (Supplementary Tables 2–5). We then searched de novo for enriched sequence motifs in predicted gene promoters (−200 and +50 base pairs (bp) from the transcription start site (TSS)), controlling for false discovery rate and validating motif robustness by analysis of spatial motif distributions (Supplementary Fig. 7a) and shifted control sequences (Supplementary Fig. 7b). In *A. queenslandica*, we selected 325 motifs for downstream analysis (Supplementary Table 7), computed promoter affinity to each motif and visualized the distribution of motif enrichments for each cell-type-specific gene module (Fig. 6a). This resulted in remarkably rich landscapes of promoter motif content, covering all inferred cell types with 16–96 distinct motifs. For example, we observed 93 distinct motifs enriched in choanocyte gene promoters, consistent with the exceptionally rich combination of 29 transcription factors associated with choanocyte-specific expression (Fig. 5d and Supplementary Fig. 5b,c). Similar analysis in *M. leidyi* (Fig. 6b; 6–82 motifs per cell type) and *T. adherens* (Fig. 6c; 29–98 motifs per cell type) confirmed that promoter motifs are significantly enriched in these organisms as well. However, comparative analysis of the degree of motif genomic specificity (Fig. 6d) and entropy (Fig. 6e) suggested that, in the ctenophore *M. leidyi*, the strength of promoter motifs and their specificity to target genes given multiple potential genomic off-targets is significantly weaker compared with *A. queenslandica* and *T. adherens*.

Our de novo discovery approach is a priori not restricted to the identification of known transcription factor binding motifs characterized in model species. Nevertheless, we found that 33% of *A. queenslandica*, 25% of *M. leidyi* and 32% of *T. adherens* motifs matched (similarity >0.7) known models retrieved from databases covering transcription factor motifs for multiple eukaryotic species (Fig. 6a–c and Supplementary Fig. 7f). This indicates that at least some of the sequence elements defining the transcription-factor–genome interface are deeply evolutionarily conserved. Remarkably, out of the 570 novel motifs that could not be matched in databases, we detected 53 conserved between at least two species (Fig. 6f and Supplementary Fig. 7g). Discovering novel motifs independently in highly diverged species serves as further validation of the robustness of the promoter signals we characterize and indicates that comprehensive characterization of the repertoire of possible transcription-factor–DNA interfaces in metazoan genomes will require further analysis of phylogenetically diverse species.

Analysis of promoter information content by predictive expression models. In multicellular animals, stable differentiated transcriptional programmes are defined by multiple cis-regulatory modules, long-range control and powerful epigenetic mechanisms. By contrast, in most unicellular eukaryotes, gene regulation involves exclusively regulatory elements that are proximal to the gene promoter. Hence, we were surprised by the high degree of proximal promoter information content in *A. queenslandica* and
Using whole-organism single-cell RNA-seq and a combination of promoter sequence motifs. Moreover, T. adhaerens shows strong evidence for distal regulatory elements. We suggest that the ctenophore mechanistic solution for defining and stabilizing cell type programmes might be more similar to the bilaterian solution, employing multiple layers of control to supplement the transcription factor combinatorics. We hypothesize that this elaborate regulation might be necessary to specify large repertoires of cell types embedded in a complex body plan such as that of ctenophores. By contrast, placozoans demonstrate the feasibility of defining and regulating multiple cell types without such strong layered architecture, but simply using a combination of transcription factors and proximal promoter regulatory elements, similarly to what is observed in unicellular eukaryotes and unlike the animal species studied to date. We expect the methodology we introduce here will facilitate multiple studies for mapping cell type regulation in diverse species in the coming years, resulting in increasingly dense phylogenetic coverage of cellular behaviours across the animal tree of life. The integrative analysis of this data will further allow a comprehensive and principled analysis of the evolutionary mechanisms leading to animal multicellularity and the genomic determinants of multifaceted transcriptional control schemes.

Methods

Animal sources, specimen dissociation and cell sorting. A. queenslandica adults and larvae were collected from Heron Island Reef, Great Barrier Reef, Queensland, Australia. Adult specimens were dissociated by placing them in a syringe and squeezing them through a 60 μm nylon mesh (fused to the end of the syringe) into calcium/magnesium-free seawater (CMFSW). Larvae were dissociated by gentle pipetting with gelatin-coated tips. M. leidyi adults originated from L. Friis-Møller, Kristineberg, Sweden. They were maintained in the laboratory in filtered seawater, with small adult specimens (~20 mm) used for dissociation. Specimens were starved for 2–3 days, with daily changes of seawater. They were relaxed briefly in 7% magnesium chloride, then rinsed twice in CMFSW. For dissociation, they were incubated in 0.25% chymotrypsin (MP Biomedicals) in CMFSW for 20 min at room temperature with constant rocking and gentle pipetting. Cells were collected by centrifugation for 10 min at 1,000 g at 16°C.

T. adhaerens (Grell strain) was cultured in the laboratory at room temperature using artificial seawater (ASW) and feeding them with the cryptophyte algae Prymnesiophyceae. Pyrenomonas helgolandica (strain SAG 28.87). Algae were obtained from the University of Göttingen algae culture collection (SAG), and cultured at room temperature in 250 ml flasks using PROV50 medium (#MKPROV50L; NCMA) and a long-wavelength fluorescent lamp. For dissociation, 30–40 animals were first transferred to a small plastic dish and, after they attached, cleaned three times with ASW. Then, ASW was replaced by CMFSW plus 10 mM ethylenediaminetetraacetic acid (EDTA) and the animals were dissociated by gentle pipetting with gelatin-coated tips.

In all cases, cells were distributed into 384-well capture plates (all coming from the same production batch) containing 2 μl of lysis solution using a FACSAria III cell sorter. The lysis solution contained 0.2% Triton and RNase inhibitors plus barcoded poly(T) reverse-transcription primers for single-cell RNA-seq. Non-cellular particles were discriminated by selecting only DRAQ5-positive cells (25 μM DRAQ5 staining; Thermo #62251), and cell doublet/multiplet exclusion was performed using forward scatter width (FSC-W) versus forward scatter height (FSC-H). Fresh cell dissociates were prepared every 2 h, and sorted plates were immediately spun down to ensure cell immersion into the lysis solution, then frozen at –80°C until further processing.

MARS-seq. Single-cell libraries were prepared as previously described. For each species, all single-cell libraries were prepared in parallel: 8,832 libraries for T. adhaerens. To further quantify this information content in cell-type-specific promoters, we implemented a simple model aiming to predict cell-type-specific expression from promoter sequences alone (see Methods). We tested the model by training on subsets of the genes and then predicting cell-type-specific gene expression from hidden promoter sequences. We found that this simple approach generated substantial predictive value in multiple A. queenslandica and T. adhaerens metacells (Fig. 6g,h and Supplementary Fig. 7c–e), despite the clear limitations of predicting combinatorial regulation using linear models. Accuracy improved as the total number of RNA molecules captured for a gene increased (Fig. 6g,h and Supplementary Fig. 7c–e), indicating that some of the inaccurancy of our predictions stems from experimental noise in the estimation of differential expression. For example, using promoter sequences alone, we could predict 50% of the A. queenslandica metacell 32 gene expression with 90% specificity (area under the curve (AUC) = 0.76) and 50% of the T. adhaerens metacell 42 gene expression with 84% specificity (AUC = 0.77). Interestingly, predictions based on promoter sequence were less powerful in the ctenophore (Supplementary Fig. 7d), suggesting an important contribution of additional, perhaps distal, regulatory elements in this group.

Characterizing distal epigenetically marked loci in M. leidyi. To test the potential contribution of long-range regulatory elements in M. leidyi and, as a control, T. adhaerens, we used indexing-first chromatin immunoprecipitation (iChIP) in these two species. We profiled chromatin extracted from whole organisms with antibodies against histone modifications associated with promoter (H3K4me2/3) and enhancer (H3K4me2-only) activities. We found that whole-organism iChIP was sufficiently sensitive to detect H3K4me2/3 enrichment in 45% of M. leidyi and 66% of T. adhaerens promoters (Fig. 6i), showing quantitatively stronger enrichment for promoters that were expressed in a larger fraction of the cells (Supplementary Fig. 8a,b). Spatial analysis showed that H3K4me3 and H3K4me2 are localized around annotated promoters at a distance scale of less than 500 bp in both species (Fig. 6j). Interestingly, we found that while in T. adhaerens the fraction of H3K4me2/3 peaks mapping in promoter regions is the same (Fig. 6k), a significant fraction of H3K4me2 in M. leidyi does not co-localize with H3K4me3 in promoters, suggesting the existence of non-promoter distal regulatory elements. Examples of epigenomic profiles (Fig. 6l and Supplementary Fig. 8c,d) and spatial mapping around distal H3K4me2 in the ctenophore (Fig. 6m) both support the existence of a distinct class of distal epigenetically marked loci in this species. Furthermore, sequence analysis revealed that these loci are 20-fold enriched for a specific GCGC-rich motif compared with promoters (fivefold compared with the genomic background) (Fig. 6n and Supplementary Fig. 8e,f). The strong chromatin signature we observe in whole-organism iChIP for this class of distal elements and the strong sequence specificity observed within it suggest that this class represents some constitutively active genomic-structural elements. Such elements may be hypothesized to perform functions that are similar to the role of CTCF in vertebrates or Beaf-32 in T. adhaerens metacells (Fig. 6g,h and Supplementary Fig. 7c–e), indicating that some of the inaccuracy of our predictions stems from experimental noise in the estimation of differential expression.

Discussion

Using whole-organism single-cell RNA-seq and a combination of sequence and chromatin analysis, we mapped differentiated transcriptional states and linked them with putative cell types in three representatives of the earliest-branching animal lineages. The unbiased approach we employed provides us the first systematic insight into early animal cell type regulatory programmes, revealing distinct cell type repertoires in adult and larval sponges, a surprisingly high diversity of cell types in M. leidyi, and the existence of multiple specialized peptidergic cell types in T. adhaerens. A combination of these cell type transcriptional atlases with chromatin and sequence analyses indicates the existence of some key differences between sponge, placozoan and ctenophore cell-type-specific transcriptional control schemes. On the one hand, A. queenslandica and T. adhaerens have fewer cell types and show remarkably specific promoter sequence motifs. Moreover, T. adhaerens shows no evidence of regulation by distal enhancer elements. On the other hand, M. leidyi has higher cell type diversity, expresses fewer specific transcription factors per cell type, and shows lower information content in gene promoters. Moreover, M. leidyi shows strong evidence for distal regulatory elements. We suggest that the ctenophore mechanistic solution for defining and stabilizing cell type programmes might be more similar to the bilaterian solution, employing multiple layers of control to supplement the transcription factor combinatorics. We hypothesize that this elaborate regulation might be necessary to specify large repertoires of cell types embedded in a complex body plan such as that of ctenophores. By contrast, placozoans demonstrate the feasibility of defining and regulating multiple cell types without such strong layered architecture, but simply using a combination of transcription factors and proximal promoter regulatory elements, similarly to what is observed in unicellular eukaryotes and unlike the animal species studied to date. We expect the methodology we introduce here will facilitate multiple studies for mapping cell type regulation in diverse species in the coming years, resulting in increasingly dense phylogenetic coverage of cellular behaviours across the animal tree of life. The integrative analysis of this data will further allow a comprehensive and principled analysis of the evolutionary mechanisms leading to animal multicellularity and the genomic determinants of multifaceted transcriptional control schemes.

Animal sources, specimen dissociation and cell sorting. A. queenslandica adults and larvae were collected from Heron Island Reef, Great Barrier Reef, Queensland, Australia. Adult specimens were dissociated by placing them in a syringe and squeezing them through a 60 μm nylon mesh (fused to the end of the syringe) into calcium/magnesium-free seawater (CMFSW). They were maintained in the laboratory in filtered seawater, with small adult specimens (~20 mm) used for dissociation. Specimens were starved for 2–3 days, with daily changes of seawater. They were relaxed briefly in 7% magnesium chloride, then rinsed twice in CMFSW. For dissociation, they were incubated in 0.25% chymotrypsin (MP Biomedicals) in CMFSW for 20 min at room temperature with constant rocking and gentle pipetting. Cells were collected by centrifugation for 10 min at 1,000 g at 16°C.

T. adhaerens (Grell strain) was cultured in the laboratory at room temperature using artificial seawater (ASW) and feeding them with the cryptophyte algae Prymnesiophyceae. Pyrenomonas helgolandica (strain SAG 28.87). Algae were obtained from the University of Göttingen algae culture collection (SAG), and cultured at room temperature in 250 ml flasks using PROV50 medium (#MKPROV50L; NCMA) and a long-wavelength fluorescent lamp. For dissociation, 30–40 animals were first transferred to a small plastic dish and, after they attached, cleaned three times with ASW. Then, ASW was replaced by CMFSW plus 10 mM ethylenediaminetetraacetic acid (EDTA) and the animals were dissociated by gentle pipetting with gelatin-coated tips.

In all cases, cells were distributed into 384-well capture plates (all coming from the same production batch) containing 2 μl of lysis solution using a FACSAria III cell sorter. The lysis solution contained 0.2% Triton and RNase inhibitors plus barcoded poly(T) reverse-transcription primers for single-cell RNA-seq. Non-cellular particles were discriminated by selecting only DRAQ5-positive cells (25 μM DRAQ5 staining; Thermo #62251), and cell doublet/multiplet exclusion was performed using forward scatter width (FSC-W) versus forward scatter height (FSC-H). Fresh cell dissociates were prepared every 2 h, and sorted plates were immediately spun down to ensure cell immersion into the lysis solution, then frozen at –80°C until further processing.

MARS-seq. Single-cell libraries were prepared as previously described. For each species, all single-cell libraries were prepared in parallel: 8,832 libraries for
A. queenslandica (13 plates for adult sponges and 10 for larvae), 6,144 for M. leidy (16 plates) and 4,224 for T. adhaerens (12 plates). That is, we employed exactly the same conditions (incubation times, temperatures and so on) and reagents in order to minimize technical factors. First, using a Bravo automated liquid handling platform (Agilent), messenger RNA was converted into complementary DNA with an oligo containing both the UMIs and cell barcodes. Unused oligonucleotides were removed by Exonuclease I treatment. Complementary DNA was pooled (each pool representing half of the original 384-well MARS-seq plate) and linearly amplified by T7 in vitro transcription, resulting in Illumina library DNA. The DNA was ligated and ligated to an oligo containing the pool barcode and Illumina sequences, using T4 single stranded DNA/RNA ligase. Finally, RNA was reverse transcribed into DNA and amplified by polymerase chain reaction (PCR). Resulting libraries were tested for amplification using quantitative PCR, and the size distribution and concentration were calculated using TapeStation (Agilent) and Qubit (Invitrogen). For each species, we added RNA-seq library to a buffer of 1 μg RNA/ml and adjusted to concentrations and sequenced to saturation (2 x 4 reads per UMI) using an Illumina NextSeq 500 sequencer and mid-output 75 cycles V2 kit (Illumina). For adult A. queenslandica, we obtained a total of 430 million reads, with an average depth of 11,000 reads per cell, and 5 reads per UMI on average. For M. leidy, we obtained a total of 506 million reads, with an average depth of 36,000 reads per cell, and 5 reads and per UMI on average. In the case of T. adhaerens, we obtained a total of 85 million reads, with an average depth of 14,000 reads per cell, and 7 reads per UMI on average.

**Processing and filtering of MARS-seq reads.** Reads were mapped into A. queenslandica, T. adhaerens and M. leidy genomes using Bowtie2 (with the parameters -D 200 -R 3 -N 1 -L 2 -i S,1,0.50) and associated with gene intervals. For each read, we assumed that the gene interval was located on the same strand as the next gene in the same strand was found. This accounts for the poor 3’ untruncated region annotation of these species, which causes many of the MARS-seq (a 3’ biased RNA-seq method) reads to map outside genes. Additionally, to account for putative unannotated genes, we defined 500-bp bins (not covered by our gene intervals) genome-wide. We retained those with ≥10 uniquely mapping reads and used them in the cell clustering process (see below). Mapped reads were further processed and filtered as previously described. UMI filtering included two components—one eliminating spurious UMIs resulting from synthesis and sequencing errors, and the other eliminating artefacts involving unlikely in vitro transcription (IVT) product distributions that were probably a consequence of second-strand synthesis or IVT errors. The minimal false discovery rate (FDR) Q value required for filtering was 0.2.

**Metacell and clustering analysis.** We used the MetaCell package (Supplementary Appendix 1) to select gene features, construct gene modules and create projected visualization of the data, using parameters as described below. We applied preliminary cell filtering based on total UMI counts using a permissive threshold of 100 UMIs (50 UMIs in the case of A. queenslandica larva, to account for the very different molecule count distributions in this sample). For gene selection, we used a normalized depth scaling correlation threshold of >0.1 (<0.05 in A. queenslandica larva and T. adhaerens). This resulted in a total UMI count of more than 100 molecules (the empirical median marker UMI count was 2,723 for the sponge, 1,013 for the catenophore, and 1,075 for the placozoan). For metacell construction, we used K = 150, a minimum module size of 30 and automatic filtering of background noise using an initial epsilon value of 0.03. Bootstrapping was performed using 1,000 iterations of resampling of 75% of the cells, leading to an estimation of co-clustering between all pairs of single cells and the identification of robust clusters based on single or grouped metacells. For 2D projections, in the A. queenslandica adult dataset, we used a k-nearest neighbours constant of 50 and restricted the module graph depth by at most 10 (A. queenslandica larva, k = 30/max degree = 3; M. leidy, k = 30/max degree = 7; T. adhaerens, k = 30/max degree = 8).

We performed manual validation and adjustment of the automatic module covers in Fig. 1 and Supplementary Fig. 4 as follows. We filtered metacells that were not enriched by at least three genes at over threefold over the median of the entire populations. Additionally, module-specific transcriptional enrichment was tested for each metacell by identifying a set of module-specific genes (top 50 genes with a fold change greater than 2) on the entire genome, and we then performed enrichment analysis using the regulatory sequences associated with each gene list, using the HOMER tool findMotifsGenome.pl (with default parameters, searching for 25 motifs and with a constant fragment size of 250bp). For each species, we grouped all the resulting de novo motifs and used the HOMER tool compareMotif.pl to filter the motifs (minimum number of hits in target sequences = 5; minimum number of hits in background sequences = 2; minimum fold enrichment = 10) and then merge redundant motifs (>0.8 similarity threshold). Additionally, in the case of M. leidy, we searched for enriched motifs in all enhancers (1,157) versus the entire genome, using a HOMER fragment size of 600 bp.

**ichIP analysis and enhancer definition.** ichIP reads were trimmed to 37 nucleotides and then mapped to the corresponding reference genome using Bowtie version 1.1.1 (ref. 15) with the parameters -v 3 -m 1. Duplicate reads were removed using SAMtools version 1.1 (ref. 16). Mapped reads were extended to 200 bp (ichIP libraries fragment size), and 1-bp-resolution coverage statistics over each of the genomes were computed.

To control for ChIP-seq sequencing coverage and variable ChIP-seq sequencing efficiency, we transformed raw reads to FDR q value to quantile values. H3K4me3 and H3K4me2 peaks were defined as regions with coverage quantiles over 0.97 (in M. leidy) or 0.94 (in T. adhaerens), merging peaks located at <200 bp. To account for mappability and assembly problems (for example, repetitive regions), we defined ‘peaks’ using input data and excluded those regions from our H3K4me3/2 peaks. Downstream analysis is included in the SI. After peak calling, we selected peaks covering downstream region of maximum q value (2 kb from any H3K4me3/2 peak) and then processed peaks using a R script called ‘peak hardcore’ to remove peaks that are not enriched by at least three genes at over threefold over the median of the entire populations.

**Sequence motif analysis.** We extracted promoter sequences using −200 or +500 bp from annotated TSSs and associated sequences with metacells whenever their gene was at least twofold expressed in the module compared with the background. We then performed de novo motif enrichment analysis for the regulatory sequences associated with each gene list, using the HOMER tool findMotifsGenome.pl (with default parameters, searching for 25 motifs and with a constant fragment size of 250bp). For each species, we grouped all the resulting de novo motifs and used the HOMER tool compareMotif.pl to filter the motifs (minimum number of hits in target sequences = 5; minimum number of hits in background sequences = 2; minimum fold enrichment = 10) and then merge redundant motifs (>0.8 similarity threshold). Additionally, in the case of M. leidy, we searched for enriched motifs in all enhancers (1,157) versus the entire genome, using a HOMER fragment size of 600 bp.

For a comparison of de novo motifs with the database, we used data from Johna et al. (ref. 17), the HOCOMOCO database (ref. 18), the JASPAR database, Drosophila melanogaster Bible database, the plant Arabidopsis database and the mouse Mus musculus database collections from Harbison et al. and Macsca et al. We computed similarities between motifs (Fig. 6 and Supplementary Fig. 7) using the motifSimilarity tool.
function of the PWMEnrich R library, which computes the normalized sum of correlations between motif position frequency matrices.

As a result of the de novo motif finding, filtering and merging, we obtained a single set of motif families. We then analysed the over-representation of specific motifs in promoters associated with metacell-specific gene modules. For a short sequence element \( s(x) \), and a position weight matrix (PWM) \( w(x) \), the standard local probability model is defined by multiplication: \( \log(P(x)) = \sum \log(w(x)) \) and the binding energy for a larger sequence element can be approximated as \( E_{\text{bind}}(x) = \log \left( \sum_{x} w(x) \right) \). For each PWM, the 0.98 quantiles of genome-wide binding energies in windows of 250 bp (same size as promoters) were determined. These quantile values were then used as thresholds to determine the motif occurrence for each PWM at each element. The enrichment level of each PWM–metacell pair was computed as the fold change between the frequency of occurrence of a motif in the metacell promoters and the frequency in the background gene set (all other genes detected in this study). Enrichments were assessed statistically using a hypergeometric test. We account for multiple testing by performing 100 random permutations of the promoter motif energy matrix, computing \( P \)-values for each permutation and using the resulting distribution to derive FDR values on the empirical enrichments. An FDR threshold of 0.02 was used for the motif enrichment visualization. Additionally, only motifs with a fold-change enrichment over 1.5 in at least one metacell, and a minimum foreground count of 5 (that is, at least 5 genes in the metacell gene set with the motif in their promoters) and background count of 100 were considered.

Finally, we performed a cross-validation analysis by dividing expressed genes into 39 species blocks and, for each of them, running the whole de novo motif discovery pipeline on the other 38 genes (training set). Using the given training set, we built a LASSO (least absolute shrinkage and selection operator) regularized linear model based on the promoter motif energies and gene expression values of the training set (80%). We then employed this model to predict the expression values of the gene test set (20%) based on the motif energies in their promoters. We then calculated the average of the obtained expression values for all expressed genes in our dataset. Receiver operating characteristic curves and AUC values were computed using the pROC R package.

**Gene functional annotation.** We used BLASTp (with the parameters -evalue \( 1 \times 10^{-9} \) and -max_target_seqs 1) to find the most similar, if any, human, fruit fly and yeast homologues (retrieved from UniProt) for each protein of the predicted *A. queenslandica*, *M. leidyi* and *T. adhaerens* predicted proteins. Additionally, we predicted for each protein the Pfam domain composition using PfamScan with the default curated protein family threshold. Transcription factors were identified using univocal Pfam domains for each structural transcription factor family. In the case of multiple transcription factor families (Homeobox, Fox, BHLH, KZIP, DM, Msd, Myb, NR, RFX, RHD, SRE, Ets, T-box and Sox), we used phylogenetic analyses for each family to classify them into specific subfamilies (together with the complete transcription factor set of an additional 10 animal species, including *Homo sapiens* and *D. melanogaster* for reference annotation). Briefly, sequences were aligned using MAFFT, the resulting analysis were manually edited, ProtTest was used to define the best-fit aminocoid substitution model in each case, and then phylogenies were computed using RAxML and PhyloBayes for maximum likelihood and Bayesian inference, respectively. We used a similar strategy to build a phylogenetic tree of *A. queenslandica* aspitzincins (Supplementary Figure 2h). We extended our search for aspitzincins to other eukaryotic and bacterial species. To this end, we used the presence of the Aspztincin_M35 domain (PF14521; Pfam) to identify aspitzincins (Supplementary Fig. 2e), extending our previous phylogenetic methods. *Proc. R. Soc. B* 276, 4261–4270 (2009).

**Data availability.** All data was deposited in Gene Expression Omnibus with the accession number GSE111068. The MetaCell package, UMI tables and annotation files are available on our group website at http://compgenomics.weizmann.ac.il/tanay/page_id=99.

Acknowledgements

We thank all members of the Tanay laboratory for comments and discussion, X. Grau-Bové for genome statistics in different species, A. Furu for help with *M. leidyi*, and H.-J. Osugi and B. Schierwater for providing T. adhaerens starting culture. Research in A.H.’s group was supported by the European Research Council Community’s Framework Programme Horizon 2020 (2014–2020) ERC grant agreement 648681 and an NSF IRF Postdoctoral Fellowship (1158629) to K.P. Research by B.M.D. is supported by the Australian Research Council. A.S.-P. was supported by an EMBO Long Term Fellowship (ALTT 841-2014). Research in A.T.'s group was supported by the European Research Council Community’s Framework Programme Horizon 2020 (2014–2020) ERC grant agreement 724824. A.T. is a Kimmel investigator.

Author contributions

A.S.-P. and A.T. conceived the project. K.P., A.H., B.M.D. and F.G. provided animal specimens and chromatin material. Z.M. and E.C. assisted with genome statistics in different species, A. Furu for help with *M. leidyi*, and H.-J. Osugi and B. Schierwater for providing T. adhaerens starting culture. Research in A.T.'s group was supported by the European Research Council Community’s Framework Programme Horizon 2020 (2014–2020) ERC grant agreement 648681 and an NSF IRF Postdoctoral Fellowship (1158629) to K.P. Research by B.M.D. is supported by the Australian Research Council. A.S.-P. was supported by an EMBO Long Term Fellowship (ALTT 841-2014). Research in A.T.'s group was supported by the European Research Council Community’s Framework Programme Horizon 2020 (2014–2020) ERC grant agreement 724824. A.T. is a Kimmel investigator.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see Authors & Referees and the Editorial Policy Checklist.

Statistical parameters

When statistical analyses are reported, confirm that the following items are present in the relevant location (e.g. figure legend, table legend, main text, or Methods section).

- n/a | Confirmed
  - The exact sample size \((n)\) for each experimental group/condition, given as a discrete number and unit of measurement
  - An indication of whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
  - The statistical test(s) used AND whether they are one- or two-sided
  - Only common tests should be described solely by name; describe more complex techniques in the Methods section.
  - A description of all covariates tested
  - A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
  - A full description of the statistics including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
  - For null hypothesis testing, the test statistic (e.g. \(F\), \(t\), \(r\)) with confidence intervals, effect sizes, degrees of freedom and \(P\) value noted
  - Give \(P\) values as exact values whenever suitable.
  - For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
  - For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
  - Estimates of effect sizes (e.g. Cohen’s \(d\), Pearson’s \(r\)), indicating how they were calculated
  - Clearly defined error bars
  - State explicitly what error bars represent (e.g. SD, SE, CI)

Our web collection on statistics for biologists may be useful.

Software and code

Policy information about availability of computer code

| Data collection | NA |
|-----------------|----|
| Data analysis   | Link to the code and usage instructions are provided, as well as detailed description of the algorithm (Appendix S1). |

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors/reviewers upon request. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research guidelines for submitting code & software for further information.

Data

Policy information about availability of data

All manuscripts must include a data availability statement. This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

All data was deposited in GEO with the accession number GSE111068. The MetaCell package, UMI tables and annotation files are available on our group website: http://compgenomics.weizmann.ac.il/tanay/?page_id=99
Field-specific reporting
Please select the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

- Life sciences
- Behavioural & social sciences
- Ecological, evolutionary & environmental sciences

For a reference copy of the document with all sections, see nature.com/authors/policies/ReportingSummary-flat.pdf

Life sciences study design

All studies must disclose on these points even when the disclosure is negative.

| Sample size | Sequencing depth and number of libraries were defined to allow support for the paper’s main conclusions (there is no "sample size" in this paper). |
|-------------|----------------------------------------------------------------------------------------------------------------------------------|
| Data exclusions | No data were excluded from the analysis. |
| Replication | NA |
| Randomization | NA |
| Blinding | NA |

Reporting for specific materials, systems and methods

| Materials & experimental systems | Methods |
|----------------------------------|---------|
| Unique biological materials | n/a |
| Antibodies | Involved in the study |
| Eukaryotic cell lines | ChIP-seq |
| Palaeontology | Flow cytometry |
| Animals and other organisms | MRI-based neuroimaging |
| Human research participants | |

Antibodies

Antibodies used
We employed antibodies against histone H3 and specific modifications of histone H3:
- anti-H3 antibody (Abcam, #ab1791)
- anti-H3K4me2 antibody (Abcam, #ab3236)
- anti-H3K4me3 antibody (Millipore, #07-473)

Validation
These antibodies have a wide species spectrum (paneukaryotic) and have been extensively used and validated in iChIP studies.

Animals and other organisms

Policy information about studies involving animals, ARRIVE guidelines recommended for reporting animal research

Laboratory animals
Placozoan (Trichoplax adhaerens) specimens were cultured in the lab.

Wild animals
- Sponge (Amphimedon queenslandica) specimens were collected from Heron Island Reef, Great Barrier Reef, Queensland, Australia.
- Ctenophore (Mnemiopsis leidyi) specimens originated from L. Friis-Møller, Kristineberg, Sweden.

Field-collected samples
Sponge and ctenophore specimens were maintained in filtered artificial sea water until further processing (dissociation for single-cell analysis or for chromatin extraction).
ChIP-seq

Data deposition

☐ Confirm that both raw and final processed data have been deposited in a public database such as GEO.

☐ Confirm that you have deposited or provided access to graph files (e.g. BED files) for the called peaks.

Data access links

May remain private before publication.

NA

Methodology

Replicates

Two replicates of iChIP experiments. Reads were pooled for downstream analysis.

Sequencing depth

12 cycles of library PCR. 37nt Paired-End Reads. For M.leidy, the total number of reads was: 21M (H3K4me2), 12M (H3K4me3) and 10M (input). For T.adhaerens, the total number of reads was: 24M (H3K4me2), 14M (H3K4me3), and 11M (input).

For T.adhaerens, % of single-mapping reads ranged 65-68%. For M.leidy, % of single-mapping reads ranged 40-42%.

Antibodies

anti-H3 antibody (Abcam, #ab1791)
### Antibodies
- anti-H3K4me2 antibody (Abcam, #ab3236)
- anti-H3K4me3 antibody (Millipore, #07-473)

### Peak calling parameters
We transformed raw coverage values to quantile values. H3K4me3 and H3K4me2 peaks were defined as regions with coverage quantiles over 0.97 (in M.leidyi) or 0.94 (in T.adhaerens), merging peaks located at <200bp. To account for mappability/assembly problems, we defined “peaks” using input data and excluded those regions from our H3K4me3/me2 peaks.

### Data quality
NA

### Software
Reads mapped using bowtie v1.1.1 with parameters -m1 -v3. Duplicated reads removed using SAMtools v1.1.
