Abstract
This work’s objective was to review the literature on biliary surgery in order to best define the surgical indications and the specifics of their management. A review of the literature from 1995 to August 2015 was conducted in Pubmed and Google Scholar.

Key words: cirrhosis, biliary surgery, cholecystitis, postoperative complications
Introduction

This chapter reports the results of surgical studies in cirrhotic patients requiring gallbladder and extrahepatic bile duct surgery. The vast majority of these studies concerned lithiasic pathology, in particular vesicular, and focused on the comparison of the different surgical approaches in this context. In contrast, very few recent studies have addressed the lithiasic pathology of the main bile duct in cirrhotic patients and even fewer have focused specifically on surgery of the extrahepatic bile ducts in cirrhotic patients in a non-lithiasic context.

Performed Research

A review of the literature from 1995 to August 2015 was conducted in Pubmed and Google Scholar, using the following keywords: "cirrhosis" in combination with one or more of the following terms: "extra-hepatic bile duct surgery; cholecystitis; cholecystectomy; laparoscopic cholecystectomy; sub-total cholecystectomy; cholecystostomy; cholangitis; endoscopic retrograde cholangiopancreatography; gallbladder stones; cholelithiasis; choledocholithiasis; common bile duct stones; common bile duct resection; and hepaticojejunostomy". Retrospective studies journals and books were also included. The articles were then analyzed and grouped according to their themes: lithiasic pathology (vesicular or main bile duct) and non-lithiasic pathology.

Surgical Indications

Reminder on the biliary pathology of the cirrhotic patient

Incidence and physiology of cholelithiasis in the cirrhotic patient

Gallstones, especially gallbladder stones, are common in patients with cirrhosis with an incidence of 9.5-29.4%, compared to 5.2-12.8% in patients without cirrhosis(1,2). Their prevalence is increasing with age, female gender, thickness of the gallbladder wall (3) and severity of complementary liver disease (4). These stones are pigmented in nature in 50 to 85% (4). This high rate is linked to a bile unconjugated bilirubin concentration increase in cirrhotic patients and seems to be due to various favourable factors such as: 1) the existence of a low ratio between bile acids and unconjugated bilirubin (5); 2) induction of an entero cycle hepatic unconjugated bilirubin favoured by chronic alcohol consumption and low protein diets; 3) chronic haemolysis linked to hypersplenism (6); and 4) biliary stasis secondary to vesicular hypotonia. Nevertheless, the clear predominance of pigmentary stones, by nature brittle and small, seems to explain the relatively low incidence of complications linked to the presence of vesicular lithiasis in cirrhotic patients. On the other hand, it is important to note that the existence of cirrhosis linked to a NAFLD (Non Alcoholic Fatty liver disease) seems to favour the development of cholesterol stones (7-9) and that it will thus probably be expected to observe an increase in the incidence and type of complications associated with these stones in the coming decades.

Complications of cholelithiasis in cirrhotic patients

Gallbladder stones are usually asymptomatic in cirrhotic patients and are more likely to be detected during follow-up ultrasound examinations. Historically, cirrhotic patients had higher rates of cholecystectomy than the general population (10,11). In a retrospective study (11), it was nevertheless pointed out that only 62% of cholecystectomized cirrhotic patients had experienced an episode of abdominal pain of biliary origin. This result could be explained by the absence of a preoperative diagnosis of cirrhosis, leading to a false interpretation of abnormal liver function tests in the context of vesicular lithiasis and of vesicular lithiasis complicated episodes.

The frequency of severe complications associated with gallbladder stones in cirrhotic patients has been evaluated in a few previous studies preceding the popularization of the laparoscopic approach in the management of
gallstone disease. This risk of complications seems to vary from 0 to 22% (6, 12, 13). It should be noted that only one study had reported a complication rate of 0% but was burdened with a loss of sight rate which did not allow a solid conclusion (12). The most commonly reported complications are chronic cholecystitis (55%) followed by acute cholecystitis (45%) and cholangitis (<5%).

A 2003 meta-analysis (14) reported that the most frequent indications of laparoscopic cholecystectomy in the cirrhotic patient were dominated by hepatic colic in 54% of cases, followed by (acute or chronic) lithiasic cholecystitis in 22% of cases, vesicular asymptomatic lithiasis in 16% of cases, acute biliary pancreatitis in 5% of cases, and lithiasic cholecystitis and, respectively, lithiasis of the main bile duct in less than 1% of cases.

Nowadays, the Tokyo consensus conference, although not specific to cirrhotic patients, is the only recommendation available to stratify the severity (Tables 1 and 2) and formalize acute cholecystitis (15) and acute cholangitis (16) management in cirrhotic patients. While some of the consensus conference’s severity criteria incorporate certain parameters common to those found in cirrhotic patients, there are, however, no studies validating the applicability of these recommendations in this specific context. Thus, while it appears obvious that the severity of the underlying liver disease plays a predominant role in the severity of acute cholecystitis and acute cholangitis in cirrhotic patients, no recommendation has specifically included this parameter in the strategy for taking care of patients suffering from these pathologies.

**Technical Specificities**

**Cholecystectomy**

In total, 34 studies published between 2000 and 2015 were analysed, including 2 meta-analyses of randomized controlled trials (17, 18), 4 prospective randomized trials (19-22), 3 comparative retrospective studies (23-25), 19 non-comparative retrospective studies (26-41), 1 meta-analysis of retrospective studies (14) and 4 reviews of retrospective studies (42-45) (Table 3). No study was specifically interested in open cholecystectomy, for which it therefore seems obsolete to

---

**Table 1. Criteria for severity of acute cholecystitis**

| Grade III: Severe acute cholecystitis |
|--------------------------------------|
| 1. Cardio-circulatory Hypotension requiring treatment with Dopamine ≥5 μg / kg per min, or norepinephrine at any dosage |
| 2. Neurological Altered consciousness |
| 3. Respiratory PaO2/FiO2 <300 |
| 4. Renal Oliguria, Serum Creatinine > 2 mg/dl |
| 5. Hepatic TP-INR > 1.5 N |
| 6. Hematologic Platelet count < 100.000/mm³ |

**Grade II: Moderate acute cholecystitis**

Defined as acute cholangitis associated with at least two of the following conditions:

- Hyperleukocytosis (> 18.000/mm³)
- Painful palpable mass or resistance in right hypochondrium
- Duration of symptoms > 72 hours
- Marked local inflammation (gangrenous or emphysematous cholecystitis, perivesicular abscess, hepatic abscess, biliary peritonitis)

**Grade I: Uncomplicated acute cholecystitis**

Defined as not meeting any of the criteria for grades II and III

Early surgical management under cover of preoperative antibiotic therapy is recommended for grade I cholecystitis. First antibiotic therapy with rapid reassessment in order to decide on secondary management (vesicular drainage or continuation of conservative treatment then delayed surgery) is recommended for grade II cholecystitis. Early surgery can also be offered in expert centres. Finally, resuscitation management combined with antibiotic therapy and vesicular drainage is recommended for grade III cholecystitis.
Table 2. Criteria for severity of acute cholangitis

Grade III: Severe acute cholangitis
Defined as acute cholangitis associated with at least one of the following dysfunctions:

1. Cardio-circulatory Hypotension requiring treatment with Dopamine $\geq 5 \mu g$ / kg per min, or norepinephrine at any dosage
2. Neurological Altered consciousness
3. Respiratory $PaO_2/FiO_2 < 300$
4. Renal Oliguria, Serum Creatinine $> 2$ mg/dl
5. Hepatic TP-INR $> 1.5 N$
6. Hematologic Platelet count $< 100.000/mm^3$

Grade II: Moderate acute cholangitis
Defined as acute cholangitis associated with at least two of the following conditions:

1. Hyperleukocytosis ($> 12.000/mm^3$) or leukopenia ($< 4000/mm^3$)
2. Fever $39^\circ C$
3. Age $\geq 75$ years old
4. Total bilirubinaemia $\geq 5$ mg/dL ($\geq 85 \mu$mol/l)
5. Hypoalbuminemia ($< 0.7N$)

Grade I: Uncomplicated acute cholangitis
Defined as not meeting any of the criteria for grades II and III

Antibiotic treatment followed by biliary drainage and treatment of aetiology is recommended for grade I angiocholites.
Antibiotic treatment with rapid biliary drainage followed by treatment of aetiology is recommended for angiocholites grade II.
Antibiotic treatment with emergency biliary drainage followed by treatment of the aetiology is recommended for grade II angiocholites.
Resuscitative care with antibiotic therapy and emergency biliary drainage followed by treatment of the aetiology is recommended for grade III angiocholites.

formalize practical recommendations based on recent literature.

In our review of the literature, 14 articles including a prospective randomized trial and 13 retrospective studies clearly reported the indications for cholecystectomy in cirrhotic patients (\textit{Annex}). The total number of patients who could be analysed was 896. The

Table 3. Level of evidence from studies reporting cholecystectomy results in cirrhotic patients between 2000 and 2015

| Level of Scientific Evidence Provided by the Literature | Before selection | After selection |
|--------------------------------------------------------|-----------------|----------------|
| Level 1 High-power randomized controlled trials         | 3               | 0              |
| Meta-analysis of randomized controlled trials           | 2               | 2              |
| Decision analysis based on well-conducted data          |                 |                |
| Level 2 Low-power randomized controlled trials          | 1               | 4              |
| Well-conducted non-randomized comparative studies        |                 |                |

indications for cholecystectomy were hepatic colic for 559 (62.4%) patients, (acute or chronic) lithiasic cholecystitis for 235 (26.2%) patients, biliary pancreatitis for 72 (8.0%) patients and other indications for 30 (3.3%) patients.

Comparison of the open approach and the laparoscopic approach

Between 2000 and 2015, the open and laparoscopic approach results comparison were reported in 2 prospective randomized trials meta-analyses, 4 prospective randomized trials, one studies retrospective meta-analysis and 4 retrospective studies (Annex 2).

Annex 2. Studies comparing the results of laparoscopic (LC) and open (OC) cholecystectomies in patients with cirrhosis

| Author, Year       | Type of study            | N (LC vs. OC) | Indications (Total: n=284) | Child-Pugh Score A/B/C (%) (Total: n=162) | Main results (laparoscopy vs. open) |

* The indication « gallbladder stones » was not judged relevant ; **Only available for laparoscopic cholecystectomies
Cholecystectomy indications were reported for 284 patients. Among these, 231 (81.4%) were operated for hepatic colic, 41 (14.4%) were operated on for acute cholecystitis and 12 (4.2%) were operated on for other aetiologies [acute biliary pancreatitis (n = 7), vesicular polyp (n = 5)]. The Child–Pugh score was specified for 145 patients having laparoscopic cholecystectomy. Of these, 118 (81.4%), 22 (15.2%) and 5 (3.5%) were ranked Child–Pugh A, B and C, respectively.

Three retrospective studies and 2 of the prospective randomized trials showed a decrease in blood loss for the laparoscopic approach compared to laparotomy. Two retrospective studies and 1 prospective randomized trial showed a reduction in the operating time for the laparoscopic approach

**Annex 3. Morbidity and mortality after laparoscopic cholecystectomies in patients with cirrhosis**

| Author, Year | Number of patients | Child-Pugh Score A/B/C (%) | Complication rate (%) | Type of complication | Mortality rate |

compared to laparotomy. Three retrospective studies and 1 prospective randomized trial showed a decrease in the rate of overall complications for the laparoscopic approach compared to laparotomy. Finally, the 4 retrospective studies and the 4 prospective randomized trials demonstrated a reduction in the length of stay for the laparoscopic approach compared to laparotomy. The meta-analysis of retrospective studies showed a reduction in operating time, blood loss and length of stay for the laparoscopic approach compared to laparotomy, but reported similar rates of complications between the two approaches. The two meta-analysis of prospective randomized trials reported a reduction in the complication rate and length of stay for the laparoscopic approach compared to laparotomy.

In total, due to better results in terms of blood loss, postoperative complications and length of stay, the laparoscopic approach should be favored in Child A and B classified cirrhotic patients, operated for “hepatic colic” (rank 1 level of evidence). For Child A and B cirrhotic patients requiring cholecystectomy secondary to acute lithiasic cholecystitis, the laparoscopic approach is associated with length of stay reduction and also seems to be preferred (rank 2 level of evidence).

**Conversion to laparotomy during laparoscopic cholecystectomy in cirrhotic patients**

Twenty-six articles published between 2000 and 2015, including 23 retrospective studies and 3 prospective randomized trials, reported conversion rates for a total of 4,029 cirrhotic patients operated on for laparoscopic cholecystectomy (Annex 3). Conversion to laparotomy was performed for 494 (12.3%) patients with rates varying from 0% to 20.8%. Conversions details were reported in 12 studies, but only

---

What are the Specifics of Biliary Surgery in Cirrhotic Patients?
involved 46 patients. The most frequently mentioned causes were the existence of a vesicular bed haemorrhage for 19 (41.3%) patients, structures insufficient visualization for 12 (26.1%) patients, the existence of adhesions for 6 (13.0%) patients, inflammation too great to allow safe laparoscopic surgery for 3 patients (6.5%) and another cause for 6 (13.0%) patients.

Only one study looked at the analysis of conversion risk factors (41). In this non-comparative unicentric retrospective study analysing 94 cirrhotic patients laparoscopically operated, 10 (10.6%) patients had required conversion to laparotomy, and the reasons were not specified. In univariate analysis, a decrease in preoperative albumin levels, an increase in the preoperative MELD score, and an increase in intraoperative blood loss were significantly associated with conversion to laparotomy. In multivariate analysis, only an increase in blood loss was significantly associated with conversion to laparotomy.

Only one study looked at the postoperative course of patients who required conversion (46). In this comparative multicentre register, 383 cirrhotic patients operated by laparotomy were compared to 2,857 cirrhotic patients laparoscopically operated. Amongst the latter, the intervention was carried out laparoscopically for 2445 (85.6%) of them and 412 (14.4%) had required conversion, and the reasons were not specified. Compared to laparotomy operated patients, conversion requiring patients had significantly lower postoperative infection rates (3.5% vs. 0.2%, p <0.001), postoperative haemorrhage (6.6% vs. 9.4%, p = 0.001) and postoperative mortality (8.3% vs. 1.3%, p <0.001). The transfusion rates were not significantly different between these two groups (19.2% vs. 14.4%, p = 0.100). Finally, the revision surgery rates were significantly higher for patients requiring conversion compared to laparotomy operated patients (2.5% vs. 1.5%, p = 0.002). Conversion requiring patients were significantly more often transfused (14.4% vs. 6.2%, p <0.001), suffered more frequent complications by postoperative haemorrhage (3.0% vs. 9.3%, p < 0.001) and required more frequent another surgery (0.8% vs. 2.5%, p <0.001). The operative mortality rates were similar between these two groups (1.4% vs. 1.3%, p = 0.676).

Finally, the postoperative infection rate was significantly higher for patients who did not require conversion compared to patients who required conversion (0.7% vs. 0.2%, p <0.001).

In total, an open route conversion in a laparoscopically operated cirrhotic patient does not seem to be detrimental to the postoperative results compared to the open approach (rank 4 level of evidence). The literature does not make it possible to determine a subgroup of patients at high risk of conversion for whom it is preferable to perform a laparotomy immediately. Apart from pneumoperitoneum contraindication patients, it is however justified to immediately consider an open cholecystectomy in cirrhotic patients with a heavy history of abdominal surgery, in particular above mezocolium area (rank 4 level of evidence).

**Technical peculiarities inherent in the cirrhotic patient and partial cholecystectomy**

The cholecystectomy inherent technical difficulties in cirrhotic patients are multiple and can be grouped as follows: 1) risk of a periumbilical collateral wound during optical trocar placement; 2) haemorrhage risk vascular adhesions; 3) liver difficult traction with Calot triangle difficult exposure; 4) vesicular pedicle risky approach in the context of portal hypertension; and 5) vesicular bed haemorrhagic dissection (47). These difficulties are even more exacerbated in acute or chronic cholecystitis operated patients.

In these circumstances, Palanivelu et al. formalized certain technical aspects of laparoscopic cholecystectomy for cirrhotic patients, such as the placement of an optical trocar in the subumbilical position; the use of Ultracision for adhesions dissection; the placement of an additional 5 mm trocar to the right of the usual epigastric trocar to allow the use of a liver retractor; performing a partial cholecystectomy to avoid significant bleeding during gallbladder bed dissection or to limit
the risk of biliary injury during cystic pedicle dissection, and, finally, the systematic placement of an abdominal drain at the end of the procedure. Thus, in their non-comparative retrospective series of 265 patients, the authors report that the use of such technical devices had made it possible to obtain 1.5% transfusion rates, a zero postoperative mortality rate and 4 days hospital stays. In addition, although 52.8% of the patients presented a bilious discharge postoperatively, this discharge had dried up spontaneously in less than 7 days for 98.6% of them. Similarly, a recent meta-analysis looking at difficult situations partial cholecystectomy results of 72.9% of laparoscopic partial cholecystectomies and 18.2% of cirrhotic patients with portal hypertension reported results similar to those observed during standard circumstances performed cholecystectomies (48).

In total, if as in laparotomy most authors perform laparoscopic cholecystectomy in the usual way, performing a partial cholecystectomy seems to be an interesting alternative in difficult situations, especially in cirrhotic patients with stigmata of portal hypertension or context of cholecystitis (rank 4 level of evidence).

**Draining the abdominal cavity**

While the installation of a drain in contact with the vesicular bed following an uncomplicated laparoscopic cholecystectomy was the subject of a meta-analysis (49) not showing any benefit of drainage in this context, the setting in place of an abdominal drain in cirrhotic patients remains controversial. On the one hand, the postoperative haemorrhagic complications increased risk in this difficult dissection context could encourage an increased monitoring during the procedure. On the other hand, the possibility of ascites fluid ascending infection risk would discourage the systematic leave of a drain.

Amongst all the articles dealing with laparoscopic cholecystectomy for cirrhotic patients, only 4 specified whether an abdominal drain had been left in place after surgery, including two prospective randomized trials and two retrospective studies (Appendix 3). The indications for cholecystectomy were

specified in 2 of these studies for a total of 85 patients and were dominated by hepatic colic (62.4%), followed by cholecystitis (37.6%). Two prospective randomized trials and a retrospective study reported systematic use of a drain in contact with the gallbladder bed, and one article reported elective use of an abdominal drain due to postoperative haemorrhage increased risk (37). A retrospective study including 30 patients reported case-by-case drainage with a 6.7% rate (36). In addition, a retrospective study reported a minimal drainage attitude without specifying the number of patients drained (39). Finally, the only study reporting the subtotal cholecystectomy results in cirrhotic patients mentioned the installation of a systematic drain during the final intervention. None of the main

* « Severe » complications ; ** Intra-operative hemorrhage
objective of the studies was to analyse the abdominal drainage relevance and none included the drainage parameter as post-operative complications risk factor.

The abdominal drainage relevance for cirrhotic patients undergoing hepatectomy has been analysed in at least two prospective randomized trials (50,51) showing that the systematic placement of an abdominal drain during intervention’s final stage was a post-operative complications risk factor. Thus, the hepatic surgery currently adopted attitude is to assess drainage placement for each individual case in patients who have required complex resection, at high risk of biliary fistula or haemorrhage.

In total, the literature does not recommend the establishment or absence of an abdominal drain after laparoscopic cholecystectomy for cirrhotic patients. A reasonable attitude nevertheless seems to leave a drain in contact with the vesicular bed on a case-by-case basis, in particular in difficult or haemorrhagic surgery context and in patients requiring a partial cholecystectomy (rank 4 level of evidence).

**Lithiasis of the main bile duct in cirrhotic patients**

A meta-analysis recently highlighted the superiority of open choledocotomy for main bile duct stones extraction in non-cirrhotic patients compared to the endoscopic approach in terms of lithiasic clearance rate without significant increase in postoperative morbidity and mortality while the laparoscopic approach brought similar results to the endoscopic approach (52).

At the present time, no study has looked at the comparison of these different approaches for cirrhotic patients. Only one study looked at the endoscopic retrograde cholangiopancreatography (ERCP) management subsequent to main bile duct obstructions in cirrhotic patients (53). This study included 538 procedures performed in cirrhotic patients, of which 35 (6.5%) for main bile duct lithiasis. If the authors reported satisfactory overall results, the lithiasic pathology ERCP results were not detailed. One study looked at the laparoscopic approach results in main bile duct lithiasis management of cirrhotic patients. In this Chinese retrospective study including 346 patients, counting 132 (38.2%) sick Child A and 214 (61.8%) sick Child B, the authors reported a 5.7% conversion rate, a 9.6% overall complication rate and a zero mortality rate (54). Although Child B patients had greater blood loss than Child A patients (85 vs. 35 mL, p <0.01), both groups had similar operating times (2.1 vs. 1.9 hours, P = 0.07), conversion rates (5.3% vs. 6.1%; p = 0.77), complication rates (10.6% vs. 8.8%; p = 0.60), residual lithiasis rates (8.3% vs. 7.1%, p = 0.65), and length of stay (4.2 vs. 4.0 days, p = 0.60). These results should nevertheless be interpreted with caution due to authors dubious probity, for they had to subsequently withdraw their publication (the reason being dual publication) (55).

Overall, view the literature data absence, it is impossible to recommend a certain surgical approach in the cirrhotic patient’s main bile duct lithiasis management, which will therefore be at best treated by interventional endoscopy (rank 4 level of evidence).

**Non-lithiasic biliary pathology of cirrhotic patients**

The therapeutic possibilities of cirrhotic patients non-lithiasic biliary pathology depend on this pathology nature (tumour, inflammatory, mechanical, viral, iatrogenic etc.) and include drug treatments use, dilation and stents placement by endoscopic or percutaneous route and other various surgical procedures.

Only one study looked at endoscopic retrograde cholangiopancreatography (ERCP) management of main bile duct obstructions in cirrhotic patients (53). In this retrospective study, 538 procedures were performed in cirrhotic patients, of which 229 (42.6%) Child A, 229 (42.6%) Child B and 80 (14.8%) Child C. The indications for ERCP were main bile duct stenosis for 379 (70.4%) patients mainly in context of CSP, main bile duct lithiasis for 35
(6.5%) patients, recurrent pancreatitis for 22 (4.1%) patients, and another cause for 102 (19.0%) patients. The post-procedural complication rate was 9.1%, of which 4.6% was acute pancreatitis, 2.8% cholangitis, 1.1% haemorrhage, 0.9% pneumonia, 0.4% duodenal perforation, 0.2% acute cholecystitis, 0.2% biliary fistula. The post-procedure mortality rate was 0.2%. The complication rate was significantly associated with the severity of the underlying liver pathology (Child A: 11.4%, Child B: 11.3% and Child C: 6.1%, p = 0.048) and the achievement of an ERCP for a pathology other than a CSP (19.8% vs. 4.5%, p <0.001). Long-term follow-up of patients was not evaluated.

Only one study was concerned with the non-liothiasic biliary pathology surgical management of cirrhotic patients spanning the 2000-2015 study period and dealt with the main bile duct stenosis management in the context of primary sclerosing cholangitis (CSP) (56). In this study including 126 patients with main bile duct stenosis or dominant stenosis linked to CSP, 61.1% had had resection of the main bile duct with hepatico-jejunal anastomosis on biliary convergence associated with bilateral intrahepatic silicone stents placement and 39.9% had had a liver transplant. Among the 77 patients with main bile duct resection, the vast majority of patients were operated due to symptomatology persistence despite biliary drainage by endoscopic or percutaneous route in 61.0% and 67.5% of cases, respectively. Only 9 (11.6%) were cirrhotic compared to 39 (79.6%) transplant patients. While the overall complication and mortality rates after main bile duct resection were 38.5% and respectively 3.9%, they were not cirrhotic patients-specific. Nevertheless, the authors reported that 2 (22.2%) cirrhotic patients had liver failure requiring liver transplantation one year after the procedure. The survival rates at 3.5 and 10 years after main bile duct resection were 85.4%, 76.4%, and respectively, 52.7%, and were significantly lower for cirrhotic patients compared to non-cirrhotic patients (60.0 %, 36.0%, 12.0% vs. 89.6%, 83.3% and 60.2%, p <0.001). Thus, the authors concluded that for cirrhotic patients with main bile duct stenosis linked to a CSP endoscopic treatment resistant, the main bile duct resection place was only very limited and that these patients should have liver transplantation priority even if liver function is preserved.

As for the rest of the non-lithiasic main bile duct pathology, no study has specifically looked at cirrhotic patients.

Overall, in the context of cirrhosis patients, main bile duct stenoses linked to primary sclerosing cholangitis must be treated with ERCP as a first intention. In the event of failure, liver transplantation should be favoured even in the presence of preserved liver function (rank 4 level of evidence). Regarding the rest of main bile duct non-lithiasic pathology, no study has specifically looked at cirrhotic patients, and it is therefore not possible to establish literature-based recommendations (rank ∞ level of evidence).

Results of Surgery: Morbidity and Mortality

Twenty-two articles published between 2000 and 2015 reported complication rates for cirrhotic patients with laparoscopic cholecystectomy (Appendix 3). Among these, there were 3 prospective randomized trials and 19 retrospective studies for a total of 1107 patients included. A total of 195 (17.6%) patients presented with at least one post-operative complication.

Sixteen articles, including 2 prospective randomized trials and 14 retrospective studies, detailed the type of postoperative complications for a total of 947 analysable patients. The most frequently reported complications were: 1) postoperative infection for 36 (3.8%) patients including 14 (1.5%) pneumopathies, 2) parietal complication for 24 (2.5%) patients, 3) postoperative ascites for 22 (2.3%) patients, 4) abdominal collection for 20 (2.1%) patients, 5) postoperative haemorrhage for 12 (1.3%) patients, and 6) biliary fistula for 7 (0.7%) patients.

Only two articles looked at postoperative complications risk factors for cirrhotic patients with laparoscopic cholecystectomy
The retrospective study by Delis et al. included 220 cirrhotic patients (Child A: 88.2% and Child B: 11.8%), of which 55.5% were operated for hepatic colic, 29.5% for acute cholecystitis and 15.0% following an episode of acute biliary pancreatitis. The postoperative complication rate was 19.1% and was significantly increased for patients with a MELD score > 13 (45.8% vs. 11.6%, p = 0.045) but not by the Child (Child) score A: 18.5% vs. 23.0% Child B, p = 0.19. The retrospective study by Quillin et al. included 94 cirrhotic patients (Child A: 64.9%, Child B: 21.3% and Child C: 2.1%), 81% of whom were operated for hepatic colic, 6% following an episode acute biliary pancreatitis, 3% for vesicular polyp, 3% for vesicular dyskinesia, 2% for acute cholecystitis and 4% for other causes. The complication rate was 34% and was significantly associated with the male sex (66% vs. 42%, p < 0.03), with a low preoperative albumin level (3.5 g/dL vs. 3.9 g/dL, p < 0.01), an increase in preoperative INR (1.2 vs. 1.1, p < 0.05), an MELD score > 10 (60% vs. 31%, p < 0.02), an increased Child score (6 vs. 5, p < 0.01), and a higher number of blood cells transfused intraoperatively (0.4 CG vs. 0.03 CG, p < 0.04).

Sixteen articles concomitantly specified the details of Child’s classification and the postoperative mortality rate (Appendix A). Hence, among the 970 patients who could be analysed, there were 766 (79.0%) Child A patients, 196 (20.2%) Child B patients and 8 (0.8%) Child C patients. In total, 8 (0.7%) patients died following the intervention, of which 3 (37.5%) patients were classified Child A, 2 (25.0%) were classified Child B and 3 (37.5%) were classified Child C. The mortality rates for patients classified Child A, B and C were thus 0.2%, 1.0% and respectively 37.5%.

Only one retrospective study looked at laparoscopic cholecystectomy mortality risk factors in cirrhotic patients (41). In this study, the postoperative mortality rate was 4.3% and significantly associated with an increase in the INR preoperative (1.4 vs. 1.1, p < 0.02), an increased Child score (8 vs. 6, p < 0.03), a higher number of blood cells transfused intraoperatively (2.3 CG vs. 0.07 CG, p < 0.04) and a higher number of intraoperatively transfused platelets (0.8 vs. 0.2, p < 0.02).

Finally, a retrospective unicentric study including 78 cirrhotic patients operated via various procedures analysed the postoperative morbidity and mortality risk factors (57). In this study, 35 (44.9%) patients were operated on for an umbilical hernia, 17 (21, 8%) of a colectomy and 26 (33.3%) patients had a laparoscopic cholecystectomy. Among these, 20 were classified Child A, 5 were classified Child B and 1 was classified Child C. The authors reported complication rates of 23.1% including 15% for patients with Child A, 40% for patients with Child B and 100% for the only Child C patient. One patient (3.8%) classified Child B but with a MELD > 15 died following the intervention. The risk factors for postoperative complication in multivariate analysis for all 78 procedures performed were: an ASA score > 3, an emergency surgery, blood loss > 150 mL, the existence of preoperative ascites, a rate bilirubin > 1.5 mg/dL and an albumin level < 30 g/l. The authors observed, moreover, that the association of a MELD score > 15 and an albumin level < 25 g/l was associated with an increase in the risk of postoperative complications by a coefficient 8 and an increase in the rate of postoperative mortality (60% vs. 14%, p < 0.01).

Overall, the existence of cirrhosis classified as Child C or with a MELD score > 15 associated with an albumin level < 25 g/l is associated with a prohibitive mortality rate and must call into question the surgical indication even if laparoscopic cholecystectomy is technically feasible (rank 4 level of evidence).

Conflict of Interest

The authors declare no conflicts of interests.
