SURVEY

A survey of subspace recycling iterative methods

This survey concerns subspace recycling methods, a popular class of iterative methods that enable effective reuse of subspace information in order to speed up convergence and find good initial guesses over a sequence of linear systems with slowly changing coefficient matrices, multiple right-hand sides, or both. The subspace information that is recycled is usually generated during the run of an iterative method (usually a Krylov subspace method) on one or more of the systems. Following introduction of definitions and notation, we examine the history of early augmentation schemes along with deflation preconditioning schemes and their influence on the development of recycling methods. We then discuss a general residual constraint framework through which many augmented Krylov and recycling methods can both be viewed. We review several augmented and recycling methods within this framework. We then discuss some known effective strategies for choosing subspaces to recycle before taking the reader through more recent developments that have generalized recycling for (sequences of) shifted linear systems, some of them with multiple right-hand sides in mind. We round out our survey with a brief review of application areas that have seen benefit from subspace recycling methods.

KEYWORDS:
Krylov subspaces, recycling, augmentation, deflation

1 | INTRODUCTION

In many applications in the computational sciences, there is a need to solve many hundreds or thousands of large-scale linear systems of the form

$$ A_i x^{(i)}_\ell = b^{(i)}_\ell \quad i = 1, 2, \ldots \quad \ell = 1, 2, \ldots $$

where the systems indexed by $i$ are available in sequence rather than simultaneously, and for each $i$ all right-hand sides indexed by $\ell$ are available simultaneously. We consider the case where consecutive coefficient matrices are sufficiently “closely related” to exploit the relationship between them. Such sequences of problems arise in a diverse array of applications; see Section 8. The coefficient matrices are often sparse or otherwise allow efficient matrix-vector multiplication in a matrix-free fashion. Generally, the dimension of the matrix is so large that matrix-free iterative methods (e.g., Krylov subspace methods or multigrid) are the most viable choice for these problems. With such an iterative method in hand, the most straightforward approach would be to apply it to each consecutive linear system, with no consideration of the relationship between systems. However, speedups in convergence and good initial guesses can be achieved by exploiting the closeness of consecutive coefficient matrices.

Abbreviations: CG – Conjugate Gradients; GMRES – Generalized Minimum Residual Method; GKB – Golub-Kahan Bidiagonalization; LSQR – GKB-based least-squares iterative solver for tall rectangular problems; HPD – Hermitian positive-definite
This survey concerns (Krylov) subspace recycling methods, a popular class of iterative methods enabling effective reuse of subspace information generated during the run of an iterative method (usually a Krylov subspace method) applied to \( \mathbf{A}^{(i)} \mathbf{x}^{(i)} = \mathbf{b}^{(i)} \), for reuse either after a cycle of iterations (for the same system) or during the iteration applied to \( \mathbf{A}^{(i+1)} \mathbf{x}^{(i+1)} = \mathbf{b}^{(i+1)} \).

### Organization of the survey

In the next section, we briefly review some basic information about Krylov subspaces methods. We include some important concepts related to residual projection methods that assist in understanding recycling strategies. In Section 2 we discuss a number of precursors and related techniques. Some of these are direct forerunners to the current recycling methods, while others were proposed with different theoretical/practical concerns in mind, but they can be interpreted in the same mathematical framework. In Section 3, we discuss a number of precursors and related techniques. Some of these are direct forerunners to the current recycling methods, while others were proposed with different theoretical/practical concerns in mind, but they can be interpreted in the same mathematical framework. In Section 4, we give an overview of the state-of-the-art augmentation-based recycling methods. We describe a general framework, posed with different theoretical/practical concerns in mind, but they can be interpreted in the same mathematical framework. In Section 5, we describe generic examples of methods in this general framework for linear systems with coefficient matrices of various structure and for different residual constraints, and we discuss effective strategies for choosing a subspace to recycle in Section 6. In Section 7, we discuss strategies to take advantage of recycling for families of systems with additional structure, in particular, solving multiple shifted systems for each coefficient matrix \( \mathbf{A}^{(i)} \). We then briefly discuss in Section 8 a variety of scientific, computational, and engineering applications which have benefited from incorporating a recycling strategy into their solvers. To conclude, we discuss some challenges which remain.

### Notation

Boldface capital letters denote matrices. Boldface lowercase letters denote vectors. Non-boldface letters (Latin and Greek) denote scalar quantities; and, when necessary, we use matching non-boldface letters to denote entries of a matrix or vector denoted by the same letter (e.g., \( h_{ij} \in \mathbb{C} \) denotes the entries of the matrix \( \mathbf{H} \)). The matrices \( \mathbf{P} \) and \( \mathbf{Q} \) are used to denote specific projectors that arise in residual projection methods. Calligraphic letters denote subspaces, and we often use a matching uppercase boldface letter to denote a matrix having that subspace as the span of its columns (e.g., the columns of \( \mathbf{Q} \)). All norms are assumed to be the \( \ell_2 \)-norm unless otherwise indicated.

### 2 ITERATIVE PROJECTION METHODS/KRYLOV SUBSPACE METHODS

Krylov subspace iterative methods are a well-known class of methods for computing an approximation \( \mathbf{t} \), to the initial error, \( \mathbf{t} \), such that for an initial guess, \( \mathbf{x}_0 \), the solution satisfies \( \mathbf{x} = \mathbf{x}_0 + \mathbf{t} \approx \mathbf{x}_0 + \mathbf{t}_j \); i.e., we are approximating \( \mathbf{t} \) which solves

\[
\mathbf{A} (\mathbf{x}_0 + \mathbf{t}) = \mathbf{b}, \quad \mathbf{A} \in \mathbb{C}^{n \times n}, \quad \mathbf{b} \in \mathbb{C}^n. \tag{2}
\]

For solving a linear system of the form eq. (2) with \( \mathbf{r}_0 = \mathbf{b} - \mathbf{A} \mathbf{x}_0 \), one builds the Krylov subspace

\[
\mathcal{K}_j (\mathbf{A}, \mathbf{r}_0) = \{ \mathbf{r}_0, \mathbf{A} \mathbf{r}_0, \mathbf{A}^2 \mathbf{r}_0, \ldots, \mathbf{A}^{j-1} \mathbf{r}_0 \}
\]

iteratively (at the cost of one matrix-vector product per iteration). At iteration \( j \), \( \mathbf{t}_j \in \mathcal{K}_j (\mathbf{A}, \mathbf{r}_0) \) is selected according to some constraint on the residual \( \mathbf{r}_j \) and \( \mathbf{x}_j = \mathbf{x}_0 + \mathbf{t}_j \) is the \( j \)th approximation. We call \( \mathbf{t}_j \) the correction and the space from which it is drawn the correction space.

An example – the Generalized Minimum Residual (GMRES) Method

To illustrate how these methods work, we focus briefly on GMRES, in which we select

\[
\mathbf{t}_j \in \mathcal{K}_j \quad \text{such that} \quad \mathbf{r}_j \perp \mathbf{A} \mathcal{K}_j (\mathbf{A}, \mathbf{r}_0). \tag{3}
\]

Methods with such a residual orthogonality constraint are called residual projection methods, because the constraint defines the projection (oblique or orthogonal) of the residual onto \( \mathcal{K}_{j+1} (\mathbf{A}, \mathbf{r}_0) \), and we call \( \mathbf{A} \mathcal{K}_j (\mathbf{A}, \mathbf{r}_0) \) here the constraint space. Characterization of these methods according to residual constraints is helpful in understanding the general structure of recycling methods. This particular constraint is equivalent to solving the residual minimization problem

\[
\mathbf{t}_j = \arg\min_{\tau \in \mathcal{K}_j (\mathbf{A}, \mathbf{r}_0)} \| \mathbf{b} - \mathbf{A} (\mathbf{x}_0 + \tau) \|, \tag{4}
\]

\[
\mathbf{A} \mathbf{r}_j = \mathbf{b} - \mathbf{A} \mathbf{x}_0, \quad \mathbf{t}_j = \mathbf{r}_j - \mathbf{A} \mathbf{r}_j, \quad \mathbf{r}_{j+1} = \mathbf{r}_j - \mathbf{A} \mathbf{t}_j.
\]
and leads to the approximation
\[ t_j = P_{K_j} e_0 \quad \text{and} \quad r_j = \left( I - Q_{K_j} \right) r_0, \] (5)
where \( P_{K_j} \) is the \((A^*A)\)-orthogonal projector onto \( K_j \) \((A, r_0)\), and \( Q_{K_j} \) is the orthogonal projector onto \( AK_j \) \((A, r_0)\).

The Arnoldi orthogonalization procedure leads to a practical implementation
The Arnoldi process builds an orthonormal basis for \( K_{j+1} \) \((A, r_0)\). Set \( v_1 = \beta^{-1} r_0 \) with \( \beta = \|r_0\| \). At iteration \( j \), we compute
\[ v_{j+1} h_{j+1,j} = A v_j - \sum_{i=1}^{j} v_i h_{i,j}, \quad \text{with} \quad h_{i,j} = v_i^* A v_j \quad \text{and} \quad h_{j+1,j} = \|A v_j - \sum_{i=1}^{j} v_i h_{i,j}\|, \] (6)
so that \( v_{j+1} \) is a unit vector. The process computes the matrices
\[ V_{j+1} = \begin{bmatrix} v_1 & v_2 & \cdots & v_{j+1} \end{bmatrix} \in \mathbb{C}^{n \times (j+1)} \quad \text{and} \quad H_j \in \mathbb{C}^{(j+1) \times j}, \] (7)
such that \( V_{j+1}^* V_{j+1} = I \), \( \text{range}(V_{j+1}) = K_{j+1} \) \((A, r_0)\), \( H_j \) is an upper Hessenberg matrix with components \( h_{i,j} \), and
\[ AV_j = V_{j+1} H_j = V_j H_j + h_{j+1,j} v_{j+1} e_j^*, \] (8)
where \( H_j \in \mathbb{C}^{j \times j} \) is simply the first \( j \) rows of \( H_j \). From (8), one can reduce the minimization (4) to a smaller \((j+1) \times j\) least-squares minimization problem
\[ y_j = \arg \min_{y \in \mathbb{C}^j} \left\| H_j y - \beta e_1 \right\| \quad \text{and} \quad t_j = V_j y_j, \] (9)

The Hermitian Lanczos process
In this case, we can use the Arnoldi process above, while exploiting that \( A \) is Hermitian and hence \( H_j = V_j^* A V_j \) is itself Hermitian. It follows that \( H_j \) is tridiagonal and \( V_j \) can be computed efficiently with the three-term recurrence
\[ v_{j+1} h_{j+1,j} = A v_j - v_j h_{j,j} - v_{j-1} h_{j-1,j}, \quad \text{and} \quad v_{2j+1} = A v_j - v_j h_{j,1}, \] (10)
with the \( h_{i,j} \) as in (3) and \( h_{j-1,j} = h_{j,j-1} \) available from the previous iteration. This recurrence is called the Lanczos recurrence, leading to the Lanczos relation (with \( T \) for tridiagonal)
\[ AV_j = V_{j+1} T_j = V_j T_j + v_{j+1} h_{j+1,j} e_j^*. \] (11)
The short recurrence (10) with tridiagonal \( T_j \) leads to a great reduction in the memory requirements of Krylov subspace methods for Hermitian linear systems. We only need to store the two most recently generated Lanczos vectors. Using the thin QR-decomposition \( T_j = G_j^{-1} R_j \) to solve (9), we can write the solution update at step \( j \) as \( t_j = V_j R_j^{-1} G_j^* e_1 \). Since the coordinate vector \( y = G_j^* e_1 \) changes only in its last coefficient from one iteration to the next, this leads to an efficient update procedure as follows. Performing the change of basis \( W_j = V_j R_j^{-1} \) leads to the additional 3-term recurrence \( w_j = r_{j,j}^{-1} (v_j - w_{j-1} r_{j-1,j} - w_{j-2} r_{j-2,j}) \) and the update \( x_j = x_0 + t_j = x_0 + W_j y = x_{j-1} + w_j \hat{y}_j \). The resulting method is called MINRES.[5]

If we assume additionally that \( A \) is Hermitian positive definite (HPD), we can minimize the error in the \( A \)-norm, \( \|t - t_j\|_A \), which corresponds to enforcing the residual constraint \( r_j \perp K_j \) \((A, r_0)\) [Sections 6.4 and 6.7.1]. Considering again the Lanczos relation (11), we have that \( T_j \) is also HPD and allows the LU decomposition \( T_j = L_j U_j \) with unit bidiagonal \( U_j \). Now taking the change of basis \( W_j = V_j U_j^{-1} \) and \( \hat{y}_j = L_j^{-1} e_1 \) and eliminating the explicit Lanczos recurrence using that \( v_{j+1} \) is just a normalization of the residual \( r_j \), we obtain the celebrated method of conjugate gradients[2].

The non-Hermitian Lanczos process
For general non-Hermitian linear systems, there exist short recurrence methods, though they generally do not lead to an orthonormal basis for the Krylov subspace[8]. Instead, one simultaneously generates dual bases for the subspaces \( K_j(A, r_0) \) and \( K_j(A^*, \hat{r}_0) \) where \( \hat{r}_0 \) is either the initial residual of a dual problem involving \( A^* \), \( r_0 \) itself, or some other non-zero vector. The biorthogonal Lanczos process is a short recurrence for iteratively generating these bases simultaneously at the cost of one application of \( A \) and one of \( A^* \) per iteration,
\[ \text{span} \{v_1, v_2, \ldots, v_j\} = K_j(A, r_0) \quad \text{and} \quad \text{span} \{\hat{v}_1, \hat{v}_2, \ldots, \hat{v}_j\} = K_j(A^*, \hat{r}_0). \] (12)
The basis vectors satisfy \( v_j^* \hat{v}_k = \delta_{jk} \) (hence biorthogonal). We show by induction that they can be generated with short recurrences. Assume that the vectors \( v_i \) and \( \hat{v}_i \) for \( i = 1, \ldots, j \) in (12) are biorthogonal and each basis has been generated using a full recurrence, that is, \( A v_i = v_i h_{i,j} + \cdots + v_{i+1} h_{i+1,j} \) and \( A^* \hat{v}_i = \hat{v}_i \hat{h}_{i,j} + \cdots + \hat{v}_{i+1} \hat{h}_{i+1,j} \), for \( i = 1, 2, \ldots, j \). To get \( \langle v_{j+1}, \hat{v}_j \rangle = 0 \)
for \( j = 1, 2, \ldots, j \) requires that \( h_{i,j} = \langle \mathbf{A} \mathbf{v}_j, \hat{\mathbf{v}}_i \rangle / \langle \mathbf{v}_j, \hat{\mathbf{v}}_i \rangle \). However, since \( \mathbf{A} \) and \( \mathbf{A}^* \) are adjoints, we have from the induction hypothesis

\[
\langle \mathbf{A} \mathbf{v}_j, \hat{\mathbf{v}}_i \rangle = \langle \mathbf{v}_j, \mathbf{A}^* \hat{\mathbf{v}}_i \rangle = 0
\]  

(13)

for all \( i < j - 1 \). Hence, \( h_{i,j} = 0 \) for \( i = 1, 2, \ldots, j - 2 \). Analogously, \( \hat{h}_{i,j} = 0 \) for \( i = 1, 2, \ldots, j - 2 \). This gives the biorthogonal Lanczos relations,

\[
\mathbf{A} \mathbf{V}_j = \mathbf{V}_j \mathbf{T}_j + h_{j+1,j} \mathbf{V}_j \mathbf{e}_j^* \quad \text{and} \quad \mathbf{A}^* \hat{\mathbf{V}}_j = \hat{\mathbf{V}}_j \hat{\mathbf{T}}_j + \hat{h}_{j+1,j} \hat{\mathbf{V}}_j \hat{\mathbf{e}}_j^*.
\]  

(14)

The Petrov-Galerkin condition \( \mathbf{r}_j \perp \mathbf{K}_j (\mathbf{A}^*, \mathbf{r}_0) \), giving rise to the biconjugate gradient (BiCG) method [10], requires at iteration \( j \),

\[
\text{Solve } \mathbf{T}_j \mathbf{y}_j = \beta \mathbf{e}_1 \quad \text{and set } \mathbf{t}_j = \mathbf{W}_j \mathbf{y}_j.
\]  

(15)

Similar to [8] for Hermitian systems, (14) allow us to define efficient short recurrence iterative methods for non-Hermitian systems using the LU decomposition \( \mathbf{T}_j = \mathbf{L}_j \mathbf{U}_j \), change of basis \( \mathbf{W}_j = \mathbf{V}_j \mathbf{U}_j^{-1} \), and setting \( \hat{\mathbf{y}} = \mathbf{L}_j^{-1} (\beta \mathbf{e}_1) \) (in general, \( \mathbf{T}_j \) and \( \hat{\mathbf{T}}_j \) are closely related, and only one LU-decomposition is computed). An analog to GMRES/MINRES also exists in this setting, called the quasi minimum residual (QMR) method [14]. At iteration \( j \), this leads to

\[
\text{Minimize } \left\| \mathbf{L}_j \mathbf{y}_j - \beta \mathbf{e}_1 \right\|, \quad \text{and set } \mathbf{t}_j = \mathbf{W}_j \mathbf{y}_j.
\]  

(16)

In cases where the action of \( \mathbf{A}^* \) is unavailable, so-called transpose free variants are available; see, e.g., [12–14]. The BiCGStab(\( \ell \)) [15] method was introduced to stabilize the oscillatory convergence pattern often exhibited by BiCG [14]. This is accomplished by alternating between \( \ell \) steps of BiCG and an \( \ell \)-cycle of GMRES, effectively building a hybrid residual polynomial from the BiCG and GMRES polynomials. Another related method is IDR(\( \ell \)) [16], which was shown to fit into the Petrov-Galerkin residual projection framework [17] and also to be a generalization of BiCGStab(\( \ell \)).

3.1 SUBSPACE AUGMENTATION AND THE STRATEGY OF DEFLATION

Subspace recycling extends ideas from the last few decades for the preservation of information between iteration cycles or between different linear systems. This is done to mitigate the effects of discarding basis vectors due to memory requirements as well as to accelerate the convergence of an iterative method using vectors generated from solving previous problems. A number of acceleration strategies occupy the same or a similar theoretical framework as augmentation-based subspace recycling, and we briefly touch upon these as well.

**What we mean by augmentation:** In this survey, we use the terms *subspace augmentation* and *augmented method* to refer to any iterative method (usually a Krylov subspace method) which uses a sum correction space \( \mathbf{U}^* + \mathbf{V}_j \), where \( \mathbf{V}_j \) is the space generated by the iterative method, and \( \mathbf{U}^* \) is the fixed augmentation space. Later, we discuss cases where \( \mathbf{V}_j \) is a Krylov subspace, and one can consider the case in which the Krylov subspace is generated by the untouched coefficient matrix/residual pair \((\mathbf{A}, \mathbf{r}_0)\) versus cases (such as in subspace recycling) in which the Krylov subspace is generated by a projected pair of the form \(((\mathbf{I} - \mathbf{Q})\mathbf{A}, (\mathbf{I} - \mathbf{Q}) \mathbf{r}_0)\), cf. Section 4.

Warm restarting and simple information reuse

The simplest information-reuse approach is called *warm restarting*. As we generate approximate solutions for the sequence of problems (1) we use the approximate solution for \( \mathbf{A}^{(i)} \mathbf{x}^{(i)} = \mathbf{b}^{(i)} \) as the initial approximation \( \mathbf{x}_j \) for the system \( \mathbf{A}^{(i+1)} \mathbf{x}^{(i+1)} = \mathbf{b}^{(i+1)} \). As consecutive systems in (1) are close (e.g., consecutive systems in a nonlinear optimization scheme), the approximate solution to system \( i \) is likely a high-quality approximation for the solution to the system \( i + 1 \).

For nonsymmetric systems, the first mention of a (non-trivial) strategy to select direction vectors for orthogonalization (to the best of our knowledge) is in [18], where the authors performed a numerical study of algorithms associated with preconditioned conjugate gradients. The authors suggest that for non-symmetric problems and a fixed (but sufficient) length recurrence, convergence is improved by retaining the search directions associated with the (relative) largest orthogonalization coefficients.

### Augmentation via flexible preconditioning

Augmentation of a Krylov subspace was proposed in a 1997 paper, which presented the idea in the framework of the flexible GMRES method [19]. Flexible GMRES is a modification of right-preconditioned GMRES that accommodates the use of a different preconditioner at each step. Recall that for a fixed right preconditioner \( \mathbf{M} \), one applies an iterative solver to the problem \( \mathbf{A} \mathbf{M}^{-1} \mathbf{y} = \mathbf{b} \) where \( \mathbf{y} = \mathbf{M} \mathbf{x} \), and for an approximation \( \hat{\mathbf{y}} \) one generates the approximation \( \hat{\mathbf{x}} = \mathbf{M}^{-1} \hat{\mathbf{y}} \).
Flexible preconditioning complicates this situation. For example, in flexible GMRES, one must store the Arnoldi vectors from (7) for a Krylov subspace of the form \( \mathcal{K}_j (\mathbf{A} \mathbf{M}^{-1}, \mathbf{r}_0) \) where \( \mathbf{M} \) is some unknown implicitly induced preconditioner, and one must additionally store a set of flexibly preconditioned Arnoldi vectors \( \mathbf{Z}_j = [\mathbf{z}_1 \ z_2 \ \cdots \ z_j] \), where \( \mathbf{z}_j = \mathbf{M}^{-1} \mathbf{v}_j \), spanning \( \mathbf{M}^{-1} \mathcal{K}_j (\mathbf{A} \mathbf{M}^{-1}, \mathbf{r}_0) \). One solves the GMRES minimization (9) for \( \mathbf{y}_j \) as before but then updates \( \mathbf{x}_j = \mathbf{x}_0 + \mathbf{Z}_j \mathbf{y}_j \).

The authors of \cite{20} pointed out that one can use this framework to augment an existing Krylov subspace. Assume we have run \( j - k \) iterations of GMRES and \( \mathbf{U} = [\mathbf{u}_1 \ \mathbf{u}_2 \ \cdots \ \mathbf{u}_k] \in \mathbb{C}^{n \times k} \) spans a \( k \) dimensional subspace \( \mathbf{U}^\perp \) to use in concert with the Krylov subspace for a correction. For the next \( k \) iterations, one can implicitly define the action of unspecified flexible preconditioners \( \mathbf{M}_{j-k+i} \) with the mappings \( \mathbf{M}_{j-k+i}^{-1} \mathbf{y}_{j-k+i} = \mathbf{u}_i \), for \( i = 1, 2, \ldots, k \). This defines a version of flexible GMRES that minimizes the residual using the constraint space \( \mathbf{A} \mathcal{K}_{j-k} (\mathbf{A}, \mathbf{r}_0) + \mathbf{A} \mathbf{U}^\perp \). This minimization is not over a direct sum of spaces. The lack of orthogonality between the subspaces reduces its effectiveness. A similar performance penalty due to lack of orthogonality was the impetus for the development of the GCROT method \cite{21}. Augmentation-type methods for ill-posed problems have been developed that rest on similar ideas \cite{22}.

**Deflation**

Deflation type methods use some of the same underlying mathematical principles as recycling methods, but they are couched in a slightly different language and towards different goals. Deflation techniques were originally proposed to treat a single problem (19). In the Ph.D. thesis \cite{2} to the residual of the projected problem, meaning residual convergence is completely determined by properties of the projected subspace. The correction equation (2), where \( \mathbf{A} \mathbf{x} = \mathbf{r}_0 \), we can directly compute \( \mathbf{P} = \mathbf{U} \left( \mathbf{U}^\ast \mathbf{A} \mathbf{U} \right)^{-1} \mathbf{U}^\ast \mathbf{r}_0 \), which can be interpreted as an approximation of the initial error in the space \( \mathbf{U}^\perp \). It remains then to approximate \( (\mathbf{I} - \mathbf{P}) \mathbf{t} \). We solve the deflation-preconditioned linear system

\[
(\mathbf{I} - \mathbf{Q}) \mathbf{A} \mathbf{t} = (\mathbf{I} - \mathbf{Q}) \mathbf{r}_0.
\]

One projector uniquely defines the other. The deflation-preconditioning process splits the initial error:

\[
\mathbf{t} = \mathbf{P} \mathbf{t} + (\mathbf{I} - \mathbf{P}) \mathbf{t}.
\]

The relation (17) implies \( \mathbf{P} \) has the form \( \mathbf{P} = \mathbf{U} \left( \mathbf{U}^\ast \mathbf{A} \mathbf{U} \right)^{-1} \mathbf{U}^\ast \mathbf{A} \), for some \( \mathbf{U}, \mathbf{\tilde{U}} \in \mathbb{C}^{n \times k} \), range (\( \mathbf{U} \)) = \( \mathbf{U}^\perp \), and range (\( \mathbf{\tilde{U}} \)) = \( \mathbf{U}^\perp \).

Since \( \mathbf{A} \mathbf{t} = \mathbf{r}_0 \), we can directly compute \( \mathbf{P} \mathbf{t} = \mathbf{U} \left( \mathbf{U}^\ast \mathbf{A} \mathbf{U} \right)^{-1} \mathbf{U}^\ast \mathbf{r}_0 \), which can be interpreted as an approximation of the initial error in the space \( \mathbf{U}^\perp \). It remains then to approximate \( (\mathbf{I} - \mathbf{P}) \mathbf{t} \). We solve the deflation-preconditioned linear system

\[
(\mathbf{I} - \mathbf{Q}) \mathbf{A} \mathbf{t} = (\mathbf{I} - \mathbf{Q}) \mathbf{r}_0.
\]

If we apply some iterative method to (19), which returns an approximation \( \mathbf{t}_j \) at iteration \( j \), then the full approximation at this step is \( \mathbf{x}_j = \mathbf{x}_0 + \mathbf{P} \mathbf{t} + (\mathbf{I} - \mathbf{P}) \mathbf{t}_j \). The residual of this approximation satisfies \( \mathbf{r}_j = \mathbf{b} - \mathbf{A} \mathbf{x}_j = (\mathbf{I} - \mathbf{Q}) (\mathbf{b} - \mathbf{A} \mathbf{x}_j) \). Thus it is equal to the residual of the projected problem, meaning residual convergence is completely determined by properties of the projected problem (19). In the Ph.D. thesis \cite{2}, it was confirmed that GCRO-based recycling schemes are indeed equivalent to particular deflation schemes for certain choices of orthogonal projectors \( \mathbf{P} \) and \( \mathbf{Q} \).

**Multigrid and domain decomposition**

The correction \( \mathbf{P} \mathbf{t} + (\mathbf{I} - \mathbf{P}) \mathbf{t}_j \) comes from the space \( \mathbf{U}^\perp + \mathcal{K}_j (\mathbf{I} - \mathbf{Q}) \mathbf{A}, (\mathbf{I} - \mathbf{Q}) \mathbf{r}_0 \). This augmented subspace interpretation of deflation-based preconditioning can be widened to also include methods involving restrictions onto and prolongation from sub-grids or coarser grids such as domain decomposition and multigrid. This has been observed, e.g., in \cite{27}. Consider, for example, a simple restriction-solution-prolongation procedure, such as a one-level multigrid V-cycle or a domain decomposition subdomain solve. Let \( \mathcal{R} \in \mathbb{C}^{n \times k} \) be the restriction operator associated to the procedure, and let \( \mathcal{P} \in \mathbb{C}^{n \times k} \) be the associated prolongation operator. Then the restriction-solution-prolongation procedure applied to (2) can be represented as

\[
\mathbf{\hat{x}} = \mathbf{x}_0 + \mathcal{P} \left( \mathcal{R} \mathcal{A} \mathcal{P} \right)^{-1} \mathcal{R} \mathbf{r}_0 \quad \text{and} \quad \mathbf{\hat{r}} = \mathbf{r}_0 - \mathcal{A} \mathcal{P} \left( \mathcal{R} \mathcal{A} \mathcal{P} \right)^{-1} \mathcal{R} \mathbf{r}_0.
\]

\( ^{1} \)It was pointed out in \cite{20} that flexible preconditioning implicitly induces exact an preconditioner \( \mathcal{M} \) defined by \( \mathcal{M}^{-1} \mathbf{v}_i = \mathbf{M}_i^{-1} \mathbf{v}_i \), for \( i = 1, 2, \ldots, j \).
If we further assume that A is Hermitian positive-definite, and that the restriction and prolongation operators satisfy the relationship $\mathcal{R} = c\mathcal{P}^*$, where $c \in \mathbb{C}$, then (20) reduces to
\[ \hat{x} \leftarrow x_0 + P_t \quad \text{and} \quad r_0 - Qr_0, \]
where $P, Q$ are projectors of the form $P = \mathcal{P} (\mathcal{P}^* A \mathcal{P})^{-1} \mathcal{P}^* A$ and $Q = A \mathcal{P} (\mathcal{P}^* A \mathcal{P})^{-1} \mathcal{P}^*$. One sees that they do satisfy (17), and these can be interpreted in the deflation-augmentation framework, where the augmentation space is now some sort of interpolation or restricted subdomain space. Indeed, it follows from the fact that this particular restriction-solution-prolongation minimizes the error in the $A$-norm that $U' = \text{range} (\mathcal{P}) = \tilde{U}$. The projectors $P$ and $Q$ are the $A$-orthogonal projector onto range ($\mathcal{P}$) and the $A^{-1}$-orthogonal projector onto range ($A \mathcal{P}$), respectively. For a general matrix $A$, the procedure becomes non-optimal with $P$ being the oblique projector onto $U'$ along $(A^* U')^\perp$, and $Q$ is the projector onto $A U'$ along $U'^\perp$. This perspective is elaborated upon in, e.g., [27] and references therein.

Bordering methods
Bordering methods were originally introduced as a means to solve a linear system by augmenting its rows and columns in a particular way to induce a singular consistent problem whose family of solutions have within them the solution to the original problem. A straightforward explanation can be found in the presentation [20]. Looking at the details, one sees elements of something that looks like augmentation and also is a precursor to deflation preconditioning.

Polynomial preconditioning
Some types of polynomial preconditioning and hybrid approaches (for example, use of the polynomial after initial $m$ GMRES its as stationary method; see e.g., [31,32]) have a strong connection to deflation methods and augmentation for a single linear system. In such methods, one runs a cycle of GMRES for a given system. After this cycle, a fixed polynomial is constructed implicitly using information from the Krylov subspace. This polynomial can either be used with a stationary iterative method or as a preconditioner for an iterative method such as GMRES.

4.1 SUBSPACE RECYCLING

When is an augmented method subspace recycling?
In this survey, we focus on a specific type of augmented Krylov subspace methods called Krylov subspace recycling methods, a moniker that communicates that the additional correction subspace was recycled from a previously generated but discarded subspace for its importance in obtaining a fast convergence rate or good initial guesses. For example, at the end of a GMRES cycle, before restarting, retaining a subspace of the generated Krylov space may accelerate convergence in the next cycle. If one is solving a sequence of the form $[1]$, retaining a subspace of the Krylov subspace generated to solve one system may accelerate solving subsequent systems. The recycled subspace may have been determined to have strongly contributed to the rate of convergence in the sense that discarding the space would let the method generate a new search space very close to the previous one or to maybe damp the influence of certain parts of the spectrum of the operator. An important aspect of subspace recycling is that, in addition to augmentation, the Krylov space is changed to complement the recycle space. As for deflation (above) the new Krylov space is generated by the operator $(I - Q)A$ and a projected residual or right hand side. The importance of this was observed in proposing the GCRO method(s); this generally avoids the (possible) stagnation problems of restarted GMRES, generates the right search space given the existing correction space, and computes the optimal solution over the sum of the correction recycle space and the generated Krylov space.

The main ideas behind Krylov subspace recycling arose from the problem that optimal Krylov methods for a fixed nonsymmetric system need all Krylov iteration (or direction) vectors in each iteration. This leads to excessive storage requirements (linear in the number of iterations) and computational work (quadratic in the number of iterations). A practical solution is to restart every, say, $m$ iterations or to truncate the set of iteration vectors and orthogonalize only against the last, say, $m$, previous iterations, leading to methods such as GMRES($m$) [4], truncated GCR($m$) [15], DIOM and DQGMRES [36]. While these strategies often work well, they also regularly lead to very slow convergence.
Augmentation based on ideas of deflation

Based on the ideas by Nicolaides for deflated CG \cite{23}, several researchers, e.g., Morgan \cite{37,38} and Erhel et al \cite{39}, proposed to use augmentation with (approximate) eigenvectors to maintain good convergence after restarting. These methods may use augmentation or a preconditioning approach to achieve the desired effect. Subsequently, Morgan proposed several improvements to the augmentation approach in \cite{37}, leading to the elegant GMRES-DR method that exploits implicit restarting of the Arnoldi recurrence to use deflation \cite{40}. Just as for GCRO, rather than augmenting the standard Krylov subspace generated by GMRES, as in \cite{37}, Morgan proposes to augment a Krylov subspace generated by \((I − Q)A\), cf. \cite{19}. Similar ideas based on implicit restarting and deflated restarts have been proposed for Lanczos-based methods \cite{40,41} and Golub-Kahan Bidiagonalization-based methods (GKB) such as LSQR \cite{42,43}. There are many other approaches which build on this type of deflated approach which incorporate flexible preconditioning \cite{45}, simultaneously treat block Krylov methods \cite{46} with inexact breakdown \cite{47}, and use deflation in a flexibly preconditioned CG approach \cite{49}.

Optimal augmentation built on GCR, i.e., GCRO-based methods

In a parallel development, independently, Eirola and Nevanlinna \cite{49} proposed a splitting-based iteration in which the splitting is updated in each step with a rank-one matrix chosen in a special way. Although the authors did not state this, with the right choices the method is equivalent to GCR \cite{53}, as observed in \cite{60}. The GMRESR method proposed in the latter paper replaces the residual as search direction in GCR with an approximation to the error computed by GMRES (or more generally by another iterative method), leading to an inner-outer iterative method. It was then observed in \cite{62} that optimality over the (direct) sum of the inner and outer correction spaces could be obtained by maintaining the right orthogonality relations, the resulting method is called GCRO. As for GMRESR, the GCRO method can be combined with any inner method, such as BiCGStab\cite{21}. The augmentation space for (basic) GCRO is spanned by the corrections computed by the sequence of inner iterations. The GCROT method extends GCRO by computing an optimal subspace to retain (recycle) for subsequent iterations. The optimality is based on considering the canonical angles between the subspaces generated by (simulated) restarted GMRES \cite{21}. An extension of GCRO for a sequence of linear systems with a fixed matrix and multiple right hand sides was presented in \cite{51}. This was extended to a sequence of linear systems where the matrix changes (slowly) with right hand sides that may or may not be close in \cite{60}, proposing the recycling GCROT and GCRODR methods. In \cite{54} this was further extended to (1) a recycling version of MINRES, (2) including approximate solutions in the recycle space to get good initial guesses, and (3) using recycling for a sequence of matrices with a number of shifts for each matrix. Additional innovations for multiple shifted systems are discussed in section \cite{7}.

More efficient versions of recycling MINRES, especially including efficient ways of computing and updating recycle spaces, were proposed in \cite{55,56}. Extensions for recycling in BiCG \cite{9}, BiCGStab \cite{14}, and IDR(s) \cite{16} have also been proposed \cite{57,58}. The idea to use projection on a search space of old solutions for initial guesses was also proposed in \cite{60}, but this paper does not involve recycling or augmentation.

Analysis

There has not been a great deal of convergence analysis of subspace recycling methods. However, several papers illuminate certain aspects of the behavior of these methods and related augmentation and acceleration strategies. An early analysis focuses on the non-optimal augmentation strategy \cite{61}. An analysis of acceleration strategies based on the principle angles between subspaces provides a comparison of strategies but not quantitative convergence bounds \cite{63}. There has been some analysis of using approximate invariant subspaces to accelerate convergence. This was touched upon in a presentation at the 2012 Householder Symposium and the associated abstract \cite{63}, and it will be elaborated further in our review paper \cite{64}. Another important way to address these questions might use the analysis of the onset of superlinear convergence in a GMRES iteration \cite{65}. Another justification supported by analytic results can be found in \cite{66}. See Section \cite{6} for further details. There is also analysis from the point of view of deflation preconditioning \cite{67,22}, and there has been a related analysis of the use of approximate deflation preconditioners constructed using previously-generated Arnoldi vectors \cite{67}.

Alternative approaches

Independently of augmentation-based subspace recycling, recycling of information was the primary point of seed-based methods. These are not deflation methods. Rather, they use the whole Krylov space generated for one system to then solve multiple simultaneously available systems. The block seed methods in \cite{68,69,70} use a block Krylov subspace to solve a subset of the systems

\footnote{The general scheme is referred to as GMRES* in \cite{22} and only with GMRES(m) as inner method as GMRESR.}
and update the remaining systems using the just-generated block Krylov subspace according to some projection or minimization. It should be noted, though, that one strategy pursued for combining subspace recycling with strategies for solving multiple shifted linear systems (cf. Section 7.1.2) built upon these methods and the analysis thereof.[22]

For groups of HPD matrices that are all close to one another, a method was proposed which is close in spirit to a recycled CG method.[22] The authors propose to reuse the entire Krylov space generated for one coefficient matrix as the augmentation space for the next, which is computationally quite expensive, and the authors suggest to restart once memory has been exhausted. The method was extended with the use of converged dominant Ritz vectors (related to the largest eigenvalues)[23] resulting in modest improvements. Both methods, as proposed, require an expensive full recursion in spite of the operator being HPD. Later, alternative subspaces for augmentation using the theory in[24] were proposed[25], following the recycling approach.

4.1 A framework

We now briefly present a general residual constraint framework through which many augmented Krylov subspace methods can be viewed. For a more complete view of this framework, see[26] which builds an understanding of these methods in terms of residual constraints on top of the existing work.[1–3] Consider two subspaces $U^*, V_j \subset \mathbb{C}^n$, where $U^*$ has fixed dimension $k$ and $V_j$ is generated by an iterative process such that at step $j$, $\dim V_j = j$. We take $U^* + V_j$ as our correction space. We can similarly construct a constraint space $\overline{U}^* + \overline{V}_j$, with $\overline{U}^*, \overline{V}_j \subset \mathbb{C}^n$ being of fixed dimension $k$ and iteratively generated with dimension $j$ at iteration $j$, respectively. We assume for simplicity that $\dim (U^* + V_j) = \dim (\overline{U}^* + \overline{V}_j) = k + j$ (direct sums). Then the general augmented projection method becomes

$$\text{select } s_j \in U^* \text{ and } t_j \in V_j \text{ such that } b - A (x_0 + s_j + t_j) \perp (U^* + \overline{V}_j).$$

We represent these subspaces with the four matrices $U, \tilde{U} \in \mathbb{C}^{n\times k}$ and $V_j, \tilde{V}_j \in \mathbb{C}^{n\times j}$, such that range($U$) = $U^*$, range($\tilde{U}$) = $\overline{U}^*$, etc. Associated to every such augmented projection method are a pair of projectors: $P = U (\tilde{U}^* A U)^{-1} \tilde{U}^* A$, the projector onto $U^*$ along $(A^* \tilde{U})^\perp$, and $Q = A U (\tilde{U}^* A U)^{-1} \tilde{U}^*$, the projector onto $A U^*$ along $\overline{U}^\perp$. From[26], we see that the constraint eq. (21) can be reformulated as the projected approximation problem whereby we take $V_j y_j$ as the approximate solution of

$$(I - Q) A t = (I - Q) r_0$$

that satisfies

$$\hat{r}_j = (I - Q) (r_0 - A V_j y_j) \perp \tilde{V}_j \quad \text{and so } \quad t_j = V_j y_j,$$

and we use $P$ to compute

$$s_j = P t - P t_j \quad \text{where } \quad P t = U (\tilde{U}^* A U)^{-1} \tilde{U}^* r_0,$$

which (when we substitute in the expression for $P$ and $t_j = V_j y_j$) leads to the construction of the full approximation at iteration $j$

$$x_j = U (\tilde{U}^* A U)^{-1} \tilde{U}^* r_0 + V_j y_j - UB y_j \quad \text{where } \quad B_j = (\tilde{U}^* A U)^{-1} \tilde{U}^* A V_j.$$

We note that the matrix $B_j$ is generally built column-by-column iteratively, and that the residual of the full problem and the projected subproblem are, in fact, equal (which means the residual norm is known without making the full update); i.e.,

$$r_j = b - A (x_0 + s_j + t_j) = \hat{r}_j,$$

which means properties of the projected coefficient matrix in (22) and the iterative method we use to approximate its solution (i.e., our choices of $V_j$ and $\tilde{V}_j$) will dictate the convergence behavior of the augmented method. Properties such as (23) and (24) are common to all subspace recycling methods. These and other characteristics which can be gleaned from the framework allow us to much more systematically design and implement a subspace recycling method.

Remark 1. Although one can choose any pair of subspaces $V_j, \tilde{V}_j$, it is important that the choice results in an efficient method. The review[26] details how to leverage this theory to obtain customized recycling methods. The greatest strength of viewing recycling methods through the lens of this framework is that it decouples the choice of the iteratively generated correction and constraint spaces $V_j$ and $\tilde{V}_j$ from the projected operator induced by the enforcing the residual constraint, i.e., the operator in (22). Previously, these methods have been considered in a context where the Krylov subspace is generated by the projected operator and an appropriate right-hand side. However, as is demonstrated in[26], this excludes useful augmentation schemes that
can indeed be described in this framework. It is this observation which enables greater latitude in the systematic design of new customized recycling methods.

Example: Recycled FOM

With the above framework and the techniques for building new methods thereof, it becomes much more straightforward to build new, customized recycling methods using specific subspaces and residual constraints. Following [1–3], we demonstrate this for a recycling FOM method. We show two choices of projectors $Q$ such that $V_j = \mathcal{K}_j ((I - Q)A, (I - Q)r_0)$ leads to a viable implementation of a recycling FOM method: in one case $Q$ is the oblique projector onto $AU$ along $U^\perp$, in the other case $Q$ is the orthogonal projector onto $AU^*$.

The first choice of $Q$ is explored in detail to produce a full implementation. In this case, we have $Q = AU(U^*AU)^{-1}U^*$, and as a consequence of (17) $P = U(U^*AU)^{-1}U^*A$. According to the framework, we apply FOM to the projected problem (19) with the modification that, during the Arnoldi process for generating a basis for $\mathcal{K}_j ((I - Q)A, (I - Q)r_0)$, we store the coefficients $B_j = (U^*AU)^{-1}U^*AV_j$ which come from applying $Q$ to $Av_i$ for each $i$. Then we solve the FOM linear problem

$$H_jy_j = \beta e_1, \quad \beta = \|(I - Q)r_0\|,$$

and at the end of the iteration we set $x_j = (x_0 + V_jy_j) + U(U^*AU)^{-1}U^*r_0 - UB_jy_j$.

5 1 PRACTICAL REALIZATIONS OF THE RECYCLING FRAMEWORK

Although the framework described in Section 4.1 can be used to understand the vast majority of subspace recycling methods, most methods which have been developed were not derived this way. There are some exceptions, such as the methods arising from earlier proposed recycling frameworks [1–3] such as [26] and the methods proposed in the forthcoming review [26] where the general framework from Section 4.1 is proposed. In this section, we give an overview of methods existing in the literature and put them into context of the framework in Section 4.1. We note that when discussing practical implementations of these methods, one must consider the developments in two adjacent communities, those for solving linear systems arising from discretizations of well-posed problems (which may be ill-conditioned due to isolated clusters of relatively small eigen- or singular values) and those arising from discretizations of ill-posed problems (which are characterized by rapidly decreasing singular values with no large, distinct gaps). There are augmented/recycling-type methods arising from both communities, where similar methods often arose by happenstance almost in parallel.

5.1 Full basis storage methods

Methods for non-Hermitian systems, which do not take advantage of a short-recurrences, require that the basis (Arnoldi) vectors from each iteration be stored until the end of the current restart cycle. Thus, recycling for these methods must be between restart cycles for a system associated to coefficient matrix $A^{(i)}$ as well as between solves for $A^{(i)}$ and $A^{(i+1)}$. Indeed, methods such as GMRES-DR [26] can be understood as recycling exclusively between restart cycles using harmonic Ritz vectors. Thus, as described in Section 4, many of these methods (see Section 5.1) can be understood as the confluence of the ideas of reuse of information between cycles and a more general passing of information between different linear systems in a systematic manner.

5.1.1 Residual minimization methods

Although they are not often explicitly derived as such, recycling (or, more generally, augmentation) methods which minimize the residual over the augmented space $U^* + V_j$ can be characterized with the well-known minimum residual constraint

$$s_j \in U^* \quad \text{and} \quad t_j \in V_j \quad \text{such that} \quad b - A(s_j + t_j) \perp A(U^* + V_j),$$

which is a specific case of the more general (21). This is the theoretical umbrella which covers all such methods. Two decisions then determine exactly which method (up to implementation) is being proposed: which Krylov subspace is represented by $V_j$ and what method of subspace downselection is being considered.

GCRO-DR/Recycled GMRES

A strength of GCRO-based approaches was that they allowed one to minimize the residual over the combination of an arbitrary subspace $U^*$ and a Krylov subspace generated from the projected coefficient matrix and right-hand side from [22]. In retrospect,
we see this as one realization of the general notion of enforcing a constraint on an augmented subspace, as in Section 4.1. For all GCRO-based methods, we have the common choice that \(V_j = K_j ((I - Q)A, (I - Q)r_0)\) with \(Q\) being the orthogonal projector onto \(A^U\).

Practically speaking, one generates via the Arnoldi process an orthonormal basis for the subspace \(K_j ((I - Q)A, (I - Q)r_0)\). Let \(C \in \mathbb{C}^{n \times k}\), \(C^*C = I\), and range(\(C\)) = \(A^U\) so that \(Q = CC^*\). Then the Arnoldi relation becomes

\[
(I - Q)AV_j = V_{j+1}\mathbf{1}_k \iff AV_j = CB_j + V_{j+1}\mathbf{1}_k
\]

where \(B_j = C^*AV_j\),

and this yields the modified Arnoldi relation

\[
A \begin{bmatrix} U & V_j \end{bmatrix} = \begin{bmatrix} C & V_{j+1} \end{bmatrix} \begin{bmatrix} I & B_j \end{bmatrix}.
\]

Using, in addition, \(r_0 = Qr_0 + (I - Q)r_0\) and \((I - Q)r_0 = v_1 \|(I - Q)r_0\|\), one can directly derive a practical implementation of the GCRO minimization yielding \(x_j = x_0 + s_j + t_j\) where,

\[
(z_j, y_j) = \arg \min_{z \in K_j \cap y \subset \mathbb{C}^k} \| \begin{bmatrix} I & B_j \end{bmatrix} \begin{bmatrix} z \\ y \end{bmatrix} - \begin{bmatrix} C^*r_0 \\ e_1 \beta \end{bmatrix} \| \text{ and } s_j = Uz_j, \ t_j = V_jy_j, \text{ where } \beta = \|(I - Q)r_0\|
\]

where \(e_1 \in \mathbb{C}^{k+j+1}\) is the 1st Euclidean basis vector. In \([29]\), it was also suggested to solve (27) blockwise, first for \(y_j\) and then set \(z_j = C^*r_0 - B_jy_j\). One sees that this is equivalent to applying GMRES directly to the projected problem \([19]\) and store in \(B_j\) the coefficients obtained from applying \(Q\) during the Arnoldi iteration \([25]\). This falls directly out of the framework in Section 4.1 but one can also observe this from the block structure of the least-squares problem \([27]\). The unknowns satisfy \(z_j = C^*r_0 - B_jy_j\), and the minimization problem reduces to \([29]\). One can then work out that for initial error \(t\),

\[
x_j = x_0 + Pt + (I - P)t_j \iff x_0 + UC^*r_0 + V_jy_j - U(B_jy_j)
\]

where \(y_j\) satisfies \([29]\) for \(H\) generated from \([25]\) and \(\beta = \|(I - Q)r_0\|\). The form of the update \([28]\) shows that this method can be implemented as a GMRES iteration applied to an equation of the form \([29]\) where we must simply store \(B_j\) as it is computed. This enables the construction of the full GCRO-DR approximation using the coefficients \(y_j\) obtained from applying GMRES to \([29]\). This is a specific realization of the general updating formula \([29]\), reinforcing the notion that all residual constraint, augmentation-based subspace recycling methods share this structure, which allows them to be understood as known iterative methods being applied to projected linear systems. Multiple authors have made this conclusion for specific subspace recycling algorithms \([1-3,34,77]\).

This setup is valid for any GCRO-based recycling method. What differentiates most GCRO-based recycling methods is how we choose a subspace of \(U^* + V_j\) to generate and \(U'_{\text{new}}\), the new recycled subspace. The GCRO-T method \([40]\) is focused on minimizing the penalty for discarding some vectors at the end of a restart cycle in a process called optimal truncation. For further details see Section 6. A number of flexible and block variants have also been proposed in the literature \([78-80]\).

The GCRO-DR method \([41]\) builds on the same GCRO-type minimization but combined with the deflated-restarting strategies of Morgan \([21]\), wherein the subspace retained between restart cycles is taken to be some harmonic Ritz vectors, e.g., generally those associated to the smallest magnitude harmonic Ritz values. There are strong associations between this strategy for solving linear systems and the implicitly restarted Arnoldi strategy for the computation of eigenvalues and eigenvectors of large, sparse matrices. Indeed, as was discussed in Section 4.1 if one looks at the forerunners of the \(*\)-DR strategies, one sees that many elements take inspiration from the implicit restarting techniques for eigen-computations \([20]\). We discuss this strategy further in the context of its effectiveness as a recycling technique along in a wider discussion of recycling strategies in Section 6. A block version of GMRES-DR has been proposed \([33,41]\) and the same is true for GCRO-DR \([80]\).

**Recycled GMRES with an alternative projector**

As has been pointed out in, e.g., \([31,39]\), there is a second variant of augmented GMRES which fits into the augmentation framework that was first proposed in \([29]\), in the context of exploring deflation-type GMRES methods. This variant fits also into the framework discussed in Section 4.1. The setup is quite similar to that of a GCRO-based method, with the main difference being that the residual minimization is performed over a obliquely projected Krylov subspace, i.e., one generated using an oblique projection. This second variant was used to propose an alternative type of recycled MINRES \([30]\) than that which is described in Section 5.2.

In this case, let \(P\) be the oblique projector onto the subspace \(U^*\) along \((A^*U^*)^\perp\) and \(Q\) be the sibling projector satisfying \([17]\), the oblique projector onto \(AU^*\) along \(U^\perp\). We use \(P\) to split the initial error \(t = Pt + (I - P)t\), observing that as before
The method has also been developed in [19] obtaining \( t_j \). The full approximation is then \( x_j = x_0 + Pt + (I - P)t_j \). This is equivalent to minimizing the full residual over the subspace \( U' + V_j \) where \( V_j = K_j ((I - Q)A, (I - Q)r_0) \) where \( Q \) is an oblique projector rather than an orthogonal projector, as in GCRO.

**Augmented GMRES for ill-posed problems**

In [83], the authors propose to reconstruct the solution of a non-Hermitian ill-posed problem of the form ([2]) over an augmented Krylov subspace as well as over a preselected space. The authors propose to do this by decomposing the problem into two subproblems using projectors. The larger subproblem is posed in a space orthogonal to the augmenting subspace and is solved using an iterative method, and the smaller problem is posed in the augmenting subspace and is solved directly. This strategy can be cast as an augmented method, as was proven in [84]. Indeed, this can be directly related to the technique of splitting the error using a projector ([18]). Applying GMRES to the projected subproblem leads to a method which is mathematically equivalent to GMRES with recycling, i.e., setting \( V_j = K_j ((I - Q)A, (I - Q)r_0) \). However, in this context, other choices of Krylov subspaces were suggested. Often, it has been shown beneficial to employ a strategy known as range-restriction, wherein one does not develop the Krylov subspace with respect to the right-hand side but rather uses a power of the operator times the right-hand side, e.g., \( V_j = K_j ((I - Q)A, (I - Q)Ar_0) \). We note that based on the work in [84], another adaptive augmented method has also been developed [88]. This body of literature is not necessarily concerned with recycling spectral information as much as it is with an augmentation space that encodes certain known features of the solution. However, strategies advocated in [89] show that recycling in the sense of GCRO-DR [11] can also be effective.

**Unprojected GMRES with range-restriction**

The fact that the modified Arnoldi iteration from [84] indeed is equivalent to a Krylov subspace iteration for the composition of the operator \( A \) and a projector was observed in [22, Remark 2.1], and this remark leads the authors to propose a modification of the augmentation method in [84]. The authors assert that augmenting an unprojected Krylov subspace allows a residual polynomial approximating the polynomial representation of the true inverse to be constructed. Using the polynomial representation of the inverse may not be the best approach for considering the effectiveness of this method, but we can evaluate this augmentation strategy nonetheless for various situations. The also assert that a poor choice of \( U' \) cause the iteration to go awry with no chance of recovery. They then propose reordering the steps of the modified Arnoldi process such that a GMRES-type iteration does reconstruct part of the approximation over a Krylov subspace generated by \( A \) rather than the projected operator of the form in ([19]). We note that with the reordering of orthogonalization steps, this method is actually closely related to the flexible GMRES-based augmentation scheme of [19] discussed in Section [3].

The method proposed in [23] can be described simply. Rather than generating the residual \( (I - Q)r_0 \) and generating a Krylov subspace with respect to the projected operator, the authors propose to generate \( K_j (A, w_0) \), where \( w_0 \in \{r_0, Ar_0\} \). After each new Arnoldi vector is generated, it is used to project the image of the augmentation space under the action of the operator away from that vector. In other words, at iteration \( j \), the algorithm generates \( \tilde{V}_j = (I - V_{j+1}V_{j+1})AU \) progressively. This leads to

\[
A \begin{bmatrix} V_j & U \end{bmatrix} = \begin{bmatrix} V_{j+1} & \tilde{V}_j \end{bmatrix} \begin{bmatrix} H & L_j \\ 0 & F_j \end{bmatrix}, \quad \text{with } L_j = V_{j+1}^*C \text{ and } F_j = \tilde{V}_j^*C.
\]

This leads to a GMRES-like iteration in which one must solve a small least squares problem of the form similar to ([5])

\[
\begin{bmatrix} y_j \\ z_j \end{bmatrix} = \arg\min_{y,z \in C} \left\| \begin{bmatrix} H & L_j \\ 0 & F_j \end{bmatrix} \begin{bmatrix} y \\ z \end{bmatrix} - \begin{bmatrix} V_{j+1} & \tilde{V}_j \end{bmatrix}^*r_0 \right\|, \quad \text{where } s_j = Uz_j \text{ and } t_j = V_jy_j.
\]

They call this method Regularized range-restricted GMRES (R3GMRES). It should be noted that this strategy also fits into the general augmentation framework, with \( V_j = K_j (A, w_0) \). Further details and elaboration on the relationship of this method to the framework in Section [4.1] can be found in the upcoming paper [22].

### 5.2 Short-recurrence-based methods

If the coefficient matrices in ([1]) are Hermitian or one employs a short recurrence method for non-Hermitian systems, then additional challenges arise for subspace recycling are different from those for GMRES and other full basis storage methods.

---

3This strategy also has been proposed for discrete ill-posed Hermitian problems (see, e.g., [85]) which itself comes from the formal minimum residual iterative regularization strategy called MR2 in the monograph [88].
Short recurrence methods do not need to restart, meaning there is no need to recycle for a subsequent restart cycle. The additional challenge with developing such a method is how to downselect the constructed basis to recycle. There is no need to recycle at a restart for the current system, but one should select a recycle space for the subsequent problem. The strategy often used is to store a running window of the $p$ most recent (Hermitian or bi-orthogonal) Lanczos vectors as columns of a matrix $V_{\text{cur}} \in \mathbb{C}^{\exp}$. Consider that we have a recycled subspace $U'_{\text{cur}}$ being used for the current system. We then have a separate recycled subspace $U'_{\text{next}}$, which is held for the next system. We initialize $U'_{\text{next}} \leftarrow U'_{\text{cur}}$. When $p$ vectors have been stored, the existing recycled subspace $U'_{\text{next}}$ is overwritten by computing a subspace of $U'_{\text{next}} + \text{range}(V_{\text{cur}})$ according to the chosen downselection criteria. The vectors in $V_{\text{cur}}$ are discarded and the matrix is filled again with the next set of $p$ Lanczos vectors. Examples of this strategy are discussed in \cite{55,66,91}.

### A-norm optimal error methods for Hermitian positive definite systems

Augmented conjugate gradient-type methods have been proposed independently in both the well- and ill-posed problems communities. Discretizations of many elliptic and parabolic partial differential equations lead to HPD discrete linear problems. For discrete ill-posed problems, one often uses a regularization of the normal equations associated to the linear problem, which generally produces a Hermitian positive-definite problem. An augmented conjugate gradients approach was first proposed in 2000 in \cite{94}. This was then followed up by \cite{95} wherein the method was improved and it was used to treat a sequence of systems with the same HPD linear system but changing right-hand sides. Some of the residuals from previous systems are proposed to span the augmentation space $U'$. An unpublished manuscript \cite{96} proposes a recycled variant of the augmented CG method that employs the strategy above, storing a fixed window of A-conjugate directions to update the recycled subspace for the next system. In the discrete ill-posed problem setting, a similar method was proposed in \cite{97}. However, the authors go further by modifying the minimization over the augmented space to transform it into a Tikhonov-type penalized minimization.

The CG algorithm can be formulated as a highly efficient algorithm by exploiting the fact that an HPD operator can define an inner product. It is important to exploit this property of the linear system also in the recycling version. Several efficient recycling-like algorithms have been proposed doing this \cite{27,94,97}. While the framework above allows us to define different recycling methods by distinct choices for the recycle correction and constraint spaces and inner product, we obtain a very efficient method by exploiting the A-inner product and using the Galerkin approach, that is, the constraint space equals the correction space. This leads to $Q = AU(U^*AU)^{-1}U^*$ and, following \cite{17}, $P = U(U^*AU)^{-1}U^*A$, which leads to several special properties. By inspection, $Q = P^*$ and $(I - Q)A = A(I - P)$ is Hermitian (the equality holds for any $Q$ and $P$ satisfying \cite{17}). Finally, we have that $(I - Q)A = A(I - P)$ is positive semi-definite, as $A$ defines an inner product: $w^*(I - Q)A_W = w^*(I - Q)(I - Q)Aw = w^*(I - P)A(I - P)w \geq 0$ and $w^*(I - Q)Aw = 0 \iff (I - P)w = 0$.

Without loss of generality, we consider henceforth the well-posed problem with A HPD and $Q$ and $P$ as defined above. Since \cite{19} is consistent, we can apply CG directly to this problem. In fact, since $\text{range}(I - Q) = U'^{-1}$, $K_j(I - Q)A(I - Q)r_0 \subseteq U'^{-1}$ and hence for any $w \in K_j(I - Q)A(I - Q)r_0$, $(I - P)w \neq 0$. Taking $v_1 = \beta^{-1}(I - Q)r_0$ with $\beta = \| (I - Q)r_0 \|$ the Lanczos relation becomes (cf. section \cite{12})

\[
(I - Q)AV_j = V_{j+1}T_j = V_jT_j + v_{j+1}h_{j+1}e^*_s.
\]

Following the above, $T_j$ is positive definite and hence the LU decomposition, $T_j = L_jU_j$ (without pivoting) exists. Hence, we can again apply the change of basis transformation $W_j = V_jU_j^{-1}$, set $\tilde{y}_j = L_j^{-1}e_1$, and run the standard CG iteration on the projected system. The (full) solution can then be computed according to eq. \cite{23}. In this case, by construction $r_j \perp \{u_1, \ldots, u_k, v_1, \ldots, v_j\}$, which proves that the error is minimized in the A-norm over the space range($U$) $\oplus$ range($V_j$).

In some alternative approaches \cite{12,94,97}, a change of basis is used that generates an A-orthogonal basis for range($U$) $\oplus$ range($V_j$), which could be advantageous for some applications.

### Minimum residual methods for Hermitian indefinite systems

Consider \cite{1} with A Hermitian and indefinite, initial guess $x_0$, and residual $r_0$. As in Section 4.1 let $U = [u_1, u_2, \ldots, u_k]$ define the recycle correction space $U' = \text{range}(U)$, and $AU = C$ with $C^*C = I$. The recycle constraint space is chosen to be $U'' = \text{range}(C)$. Hence, $Q = CC^*$ and $P = UC^*A$, which gives $Pt = UC^*r_0$. Recycling MINRES (rMINRES) \cite{98} works by applying MINRES to approximately solve the system $(I - Q)At = (I - Q)r_0$ for an approximation to the update $t$. Since $K((I - Q)A, (I - Q)r_0) \subset \text{range}(I - Q)$, $(I - Q)A : \text{range}(I - Q) \rightarrow \text{range}(I - Q)$, and $A = A^*$, we have for all $z_1, z_2 \in \text{range}(I - Q)$,

\[
\langle (I - Q)Az_1, z_2 \rangle = \langle (I - Q)A(I - Q)z_1, z_2 \rangle = \langle z_1, (I - Q)A(I - Q)z_2 \rangle = \langle z_1, (I - Q)Az_2 \rangle.
\]

---

\*It has been shown that CG applied to this problem with an appropriate early stopping rule satisfies the formal definition of regularization; see \cite{27} and \cite{97} for details. Indeed, augmentation-type methods fitting into the framework in Section 4.1 have been shown to also satisfy the formal definition of a regularization in \cite{97}.\*
So, \((I-Q)A\) is self-adjoint (‘Hermitian’) over \(\mathcal{K}((I-Q)A,(I-Q)r_0)\), and we use the Hermitian Lanczos process \(^{10}\) to get

\[(I-Q)AV_j = V_{j+1}T_j \quad \iff \quad AV_j = CB_j + V_{j+1}T_j,
\]

with \(B_j = C^*AV_j\). As for standard MINRES, we can apply a change of basis, \(W_jR_j = V_j\), using the thin QR decomposition \(T_j = G_jR_j\), set \(\tilde{y} = G_j^*e_1\|\|(I-Q)r_0\|\|\), and during the iteration use the (partial) solution update \(x_j = x_{j-1} + w_j\tilde{y}_j = x_0 + W_j\tilde{y}_j\), where \(T_j = W_j\tilde{y}_j\). At the end of the iteration, we set

\[x_j = x_j + Pt - Pt_j = x_0 + W_j\tilde{y}_j + UC^*r_0 - UB_j(R^{-1}\tilde{y}_j).
\]

This approach postpones all \(U\) updates during the iteration to a single update at the end, which saves \(O(kn)\) work per iteration\(^ {35}\). Several other efficiency improvements are discussed in \(^{56,58}\). This includes a change of basis that allows to discard the columns of \(B_j\) as we go (possibly important if many iterations are required) and very efficient recurrences to compute a recycle space.

**Bi-orthogonal Lanczos-based methods and Transpose-free Variants**

For non-Hermitian system matrices, we consider BiCG and BiCGstab-based methods\(^ {58,91,99,100}\). Obviously, recycling versions of QMR\(^ {60}\) and TFQMR\(^ {13}\) can developed as well. Recently, a recycling IDR(s) variant was developed\(^ {69}\).

**Recycling BiCG**

We modify the BiCG algorithm to use recycle spaces. Here, we follow the approach chosen in \(^ {91}\). Let range(\(U\) = \(\mathcal{U}\) be the chosen recycle (correction) space for the primary linear system \(^ {11}\) and range(\(U\)) = \(\mathcal{U}\) be the chosen recycle correction space for the dual system. Moreover, we choose \(U\) and \(\hat{U}\) such that \(C = AU\) and \(\hat{C} = A^*\hat{U}\) satisfy \(\hat{C}C = D_j\) is real, diagonal, and invertible, i.e., \(\hat{C}\) and \(C\) are bi-orthogonal. This can always be done (for example using the SVD\(^ {91}\) or an LDU decomposition), although it may require reducing the dimension of the recycle spaces if \(D_j\) had one or more zeros on the diagonal. We define \(Q = CD^{-1}_c\hat{C}^*\) and \(P = UD^{-1}_c\hat{C}^*A\). Following the discussion on the non-Hermitian Lanczos process in section\(^ {2}\) we build dual bases for the subspaces \(\mathcal{K}_j((I-Q)A,(I-Q)r_0)\) and \(\mathcal{K}_j((I-Q^*)A^*,(I-Q^*)^2\tilde{r}_0)\) where \(\tilde{r}_0\) is either the initial residual of a dual problem involving \(A^*, r_0\) itself, or some other non-zero vector. This implies that the recycle constraint space is given by \(\tilde{U} = \text{range}(\hat{C})\), and the recycled constraint space for the dual problem, if defined, is range(\(C\)). Note that \((I-Q)A : range(\hat{C})^\perp \to range(\hat{C})^\perp\) and \((I-Q^*)A^* : range(C)^\perp \to range(C)^\perp\), and we have for any \(w \in range(\hat{C})^\perp\), \(\tilde{w} \in range(C)^\perp\) that

\[
\langle (I-Q)Aw, \tilde{w} \rangle = \langle (I-Q)A(I-Q)w, \tilde{w} \rangle = \langle w, (I-Q^*)A^*(I-Q^*)^2\tilde{r} \rangle = \langle w, (I-Q^*)A^*\tilde{w} \rangle.
\]

So, \((I-Q)A\) and \((I-Q^*)A^*\) act as adjoints over the primary and dual Krylov spaces, and we can again apply a coupled three-term recurrence as in Section\(^ {2}\)

\[(I-Q)AV_j = V_{j+1}T_j \quad \text{and} \quad (I-Q^*)A^*\tilde{V}_j = \tilde{V}_{j+1}\tilde{T}_j.
\]

As for the standard BiCG discussion, we consider here the updates for the primary system; the updates for the dual system (if needed) can be computed analogously. We compute (if it exists) the LU-decomposition \(T_j = L_jU_j\), use the change of basis \(W_j = V_jL_j^{-1}\), and set \(\tilde{y}_j = L_j^{-1}e_1\tilde{c}\). This allows us to eliminate the Lanczos vectors and update

\[t_j = t_{j-1} + w_j\tilde{y}_j.
\]

The corresponding full solution is given by

\[x_j = x_0 + t_j + Pt = x_0 + t_j + UD^{-1}_c\hat{C}^*r_0 - UD^{-1}_c\hat{C}^*AW_j\tilde{y},
\]

Only \(t_j\) is updated during the iteration. The updates in the \(U\) direction are done after the final iteration, while the vector \(D^{-1}_c\hat{C}^*AW_j\tilde{y}\) can be updated during the iteration (without computing \(AW_j\tilde{y}\))\(^ {21}\). The matrices for the generalized eigenvalue problem that defines these subspaces can be constructed efficiently using recurrences\(^ {21}\).

One can develop a recycling BiCGStab based on recycling BiCG using the polynomials defining the iteration vectors following\(^ {14}\); see\(^ {58}\). This leads to a recycling BiCGStab with the matrix \((I-Q)A\) and \(Q\) as defined above. However, one can also take \(Q\) as for recycling GCROT above, based on a single recycling correction space \(\mathcal{U}\), yielding \(Q = CC^*\); see\(^ {58}\) and\(^ {100}\), which includes an application where this approach is particularly useful.

**LSQR-based methods**

This survey has focused on recycling methods for linear problems with square coefficient matrices. However, the framework of Section\(^ {4.1}\) is not restricted to square matrices or even matrix equations. It is shown in\(^ {69}\) that we can extend this framework to
Hilbert space operator equations $Tx = y$ where $T : \mathcal{X} \rightarrow \mathcal{Y}$ is a linear mapping between two abstract Hilbert spaces. One can approximate the solution using a Petrov-Galerkin residual constraint posed in $\mathcal{Y}$, with the correction spaces $\mathcal{U}$, $\mathcal{V}_j \subset \mathcal{X}$ and the constraint spaces $\tilde{\mathcal{U}}$, $\tilde{\mathcal{V}}_j \subset \mathcal{Y}$. This Hilbert space framework is also used in [21] to prove that augmentation methods satisfy the formal definition of a regularization method in the infinite-dimensional ill-posed problems setting.

One realization of this more general notion of recycling methods arises when we have a linear system with a tall, skinny matrix wherein we are seeking the least-squares solution. Consider the (possibly inconsistent) linear system

$$Gx \approx f \quad \text{where} \quad G \in \mathbb{R}^{m \times n} \quad \text{and} \quad m > n$$

The LSQR method is a short-recurrence Golub-Kahan bidiagonalization (GKB) method [53] which progressively solves

$$t_j = \arg \min_{t \in \mathcal{K}_j (G^*G, Gr_0)} \| b - G (x_0 + t) \| \quad \text{where} \quad r_0 = f - Gx_0,$$

which can be shown to be equivalent to the residual constraint formulation

$$\text{select } t_j \in \mathcal{K}_j (G^*G, G^*r_0) \quad \text{such that} \quad f - G(x_0 + t_j) \perp GG^*\mathcal{K}_j (G^*r_0).$$

The efficient progressive formulation of the algorithm arises from the fact that it is possible to generate simultaneously via short recurrences orthonormal bases for the spaces $\mathcal{K}_j (G^*G, G^*r_0)$ and $\mathcal{K}_j (G^*r_0)$ via the GKB.

With this formulation, one sees that it is possible to impose residual correction/constraint conditions over sums of spaces for this problem just as in the square problem case [21]. The main challenge then is to choose projected Krylov subspaces $\mathcal{V}_j$ and $\tilde{\mathcal{V}}_j$ for the iteratively generated parts of the correction and constraint spaces, respectively, which are related such that orthonormal bases can be generated via GKB-type short recurrences. This has not been explored extensively in the literature, to our knowledge. For acceleration of convergence for a single problem, a deflated-restart-type method based on the theory presented for GMRES-DR [25] was proposed [42]. A forthcoming paper for sequences of regularized least-squares problems explores one particular strategy for choosing the projected Krylov spaces $\mathcal{V}_j$ and $\tilde{\mathcal{V}}_j$ appropriately to ensure that the orthonormal bases can be generated via the GKB [26] and is further explored in the upcoming review [64].

6 WHAT TO RECYCLE

It is difficult to make general prescriptions about which subspaces to recycle because this depends on so many factors connected to the specific problem being solved. We break down the different choices proposed currently in the literature: approximate eigenvector augmentation, POD-type strategies, optimal truncation, and spaces from approximate solutions.

Approximate solution augmentation

In [54] solutions from previous nonlinear iterations are recycled to obtain good initial guesses in subsequent problems. The success of this approach is problem dependent. If the right hand sides do not change (much) from one linear system to the next (as is the case in [54]) and the coefficient matrices are close, this typically produces good initial guesses.

Approximate eigenvector augmentation

As discussed in Section 4, there has been limited analysis up to now on approximate eigenvector augmentation (see, e.g., [2, 63, 66] and our forthcoming review [64]), but there is strong evidence of the effectiveness of this strategy based on actual results for application problems. As these methods have often been shown to be equivalent to a deflation strategy, analysis pertaining to exact eigenvector deflation is also useful to study.

One rationale for augmenting with approximate eigenspaces is connected to the convergence theory for Krylov subspace methods. If $U^*$ is an approximate eigenspace, then the projector $(I - Q)$ is an (in this case orthogonal) projector onto $(A U^*)^\perp$, and iterations during a cycle of GCRO-DR take place in $(A U^*)^\perp$. Thus, the projector $(I - Q)$ may have the effect of damping possible negative influence on convergence speed of the approximated invariant subspace (following from the theory introduced in [53]), leading to an accelerated convergence. Care must be taken, however, as it has been shown that residual convergence need not necessarily be connected to the spectral properties of the coefficient matrix [103].

Additionally, if two matrices $A^{(i)}$ and $A^{(i+1)}$ are “close enough”, then particular respective invariant subspaces may also be close. For some differential operators (such as an elliptic operator), the higher-frequency eigenmodes are associated with the larger eigenvalues, and this property usually is inherited by the discretized matrix. If the sequence of linear systems is induced by local changes in the matrix entries, then the changes to the invariant subspaces associated to the higher-frequency eigenvectors...
(with larger eigenvalues) dominate. The details are quite technical; so we direct the reader to [106] where this was discussed and quantified for the problem under consideration. Conversely, for certain integral operators, one would want to recycle the approximate eigenvectors associated to the larger Ritz values, again to capture the low-frequency eigenvectors.

Approximate singular vector augmentation
In [104], it has been recently proposed that one can also observe convergence speedups by recycling approximate singular vectors rather than eigenvectors, based on some analysis in [105] that the residual having large components in the left singular vectors can cause reduced convergence speed. The authors thus propose to use a Ritz-type approximation of the left singular vectors (i.e., eigenvectors of $A^*A$) and recycle some of them.

Optimal truncation
In [21], a method is proposed to mitigate the effects of restarting after a cycle of GMRES, wherein the entire Krylov subspace from the previous cycle is discarded, meaning we are disregarding orthogonality with respect to the discarded subspace. This causes the characteristic reduced convergence rate one sees with restarted GMRES as compared to full GMRES. In [21], the author develops a model to characterize this delay (called “residual error” in the paper). One can again hearken back to the difference between the steepest descent method and CG as in Section 4 to understand this strategy. Restarting necessitates ignoring orthogonality with respect to the previously generated search space, and one way to interpret the so-called residual error caused by this is that the next cycle of GMRES induces a minimization over the new Krylov subspace which, since it is not orthogonalized against the previous, undoes some of the improvement in the residual along directions from the previous Krylov subspace. At worst, this can cause total stagnation (it is a residual minimization method; so there will be no increase in residual norm), and it generally is known to cause a slowdown in convergence. The GCROT method seeks to mitigate this problem with the described strategy, by maintaining orthogonality to some portion of the previously generated Krylov subspace.

This is achieved via the assumption that subspaces which were important (for speed of convergence) to maintain orthogonality against will continue to be important. Thus, for a cycle with length $m$, one studies the convergence during the last $s < m$ iterations of the cycle and compares that to the slower convergence which would have occurred had a dimension $k$ subspace been neglected during the Arnoldi orthogonalization in those last $s$ iterations. One can determine the dimension $k$ subspace that would have caused the most delay had orthogonality against that space been neglected [21]. This subspace is then chosen to be retained for the next cycle in a process called optimal truncation. The model works just as well if we are selecting a subspace of an augmented Krylov subspace of the form $U^* + V_j$, where $V_j$ is a projected Krylov subspace of the form $K_j (I - Q)A, (I - Q)r_0$. To recycle between consecutive linear systems with respective coefficient matrices $A^{(j)}$ and $A^{(j+1)}$ one can also employ this strategy: if consecutive systems are “close enough”, typical optimal truncation will still confer benefits associated with maintaining orthogonality to the truncated subspace.

POD-type strategies
In the setting of recycled GMRES for a non-Hermitian family of shifted systems, the notion of using a POD-type strategy has actually been alluded to in one of the numerical experiments [106, Section 6.6]. However, the author did not call this a POD strategy, and this was not expanded upon. This strategy takes advantage of the fact that for the test examples (coming from lattice quantum-chromodynamics application problems) the solutions for all shifted systems with shifts in a positive interval suitably away from zero depend smoothly on the shift. Thus according to the theory of Kressner and Töber [22]; cf. Section 7.5 for more details.

More explicitly, a recycled CG method was proposed in which a subspace of the correction space is selected for retention using a strategy based on techniques from model order reduction [108]. If one is solving a sequence of HPD problems, and $j - 1$ systems have already been solved, the authors propose that one collect specially chosen snapshot vectors accumulated from the first $j - 1$ system solves and use them to generate the POD-subspace with which to augment when applying CG to system $j$. This subspace is generated by approximately minimizing the operator-norm-distance between the true solution and its projection onto the wanted POD subspace.

7 EXPLOITING OPERATOR STRUCTURE AND MULTIPLE RIGHT-HAND SIDES

Sometimes, the sequence of coefficient matrices $A^{(i)}$ have additional structure or for each $i$ we actually have a parameterized set of matrices $A^{(i)}(s)$, each of which is associated to a linear system. Furthermore, there may be many right-hand sides for a single
system matrix, or slightly different right-hand sides for a sequence of related matrices. Such problems present additional challenges for adapting recycling. Most often, this takes the form of families of matrices which have some linear shifting structure, although we do consider more general parameter dependence in Section 7.5. The most general formulation of a family of linear systems with linear shift structure is

\[(A^{(i)} + \gamma \epsilon E)x^{(i,\epsilon)} = b^{(i,\epsilon)}, \quad \gamma \epsilon \geq 0, j = 1, \ldots, j_*; k = 1, \ldots, k^*; \epsilon = 1, \ldots, L.\]  

Consider, for example, that in general, \(\text{Range}(A + \gamma I)U \neq \text{Range}(AU)\) unless \(U\) is an invariant subspace of \(A\); so even something as seemingly innocuous as an identity shift (i.e., \(E = I\)) can cause difficulties with any solver that falls into the recycling framework. However, these problems do have structure that can be exploited which allows for extensions in the spirit of recycling.

In the following, we split the discussion of recycling for systems with additional structure into scalar identity shifts, scalar non-identity shifts, and more general continuous parameter dependence. For scalar identity shifts, the discussion is further split into shift-dependent right-hand sides, right-hand sides independent of shifts, and multiple right-hand sides in addition to shifts. Note that these categories are not mutually exclusive, since some methods will transform a family shift-independent right-hand sides into one for which there is shift-dependence. Such cases are noted in Section 7.1 with forward references to relevant sections.

### 7.1 Scalar shifted matrices \(\{A + \gamma \epsilon I\}_{\epsilon = 1}^L\) whose RHS changes with each shift

In this subsection, we consider \(E = I\) for a single right-hand side and fixed system matrix in the sequence, which allows us to drop indices \(i, j\) in (32). We denote \(x_0^{(\epsilon)}\) to be the initial approximation for the shifted system with shift \(\gamma \epsilon\), \(u_i^{(\epsilon)}\) to be the correction generated for this shift at iteration \(j\), and \(r_j^{(\epsilon)} = b^{(\epsilon)} - (A + \gamma \epsilon I)(x_0^{(\epsilon)} + u_i^{(\epsilon)})\) to be the residual for the system associated to shift \(\epsilon\). A property of Krylov subspaces which makes them attractive for treating a family of shifted systems is that for a given seed vector, the subspace is invariant with respect to scalar shifts by the identity of the coefficient matrix. More generally,

\[K_j(A + \gamma \epsilon I, u) = K_j(A + \gamma \epsilon I, \tilde{u})\]  

where \(\tilde{u} = \omega u\) for some \(\omega \in C \setminus \{0\}\) and for any nonzero values of \(\gamma \epsilon\) and \(\gamma \epsilon\). If \(b^{(\epsilon)} = b\) and \(x_0^{(\epsilon)} = 0\) for all \(\epsilon\), such as with systems arising in lattice quantum-chromodynamics \([110]\) and Tikhonov regularization \([110]\), we can design (non-recycling based) solvers to take advantage of this shift invariance. In this subsection, we are concerned with reusing information when the right-hand sides do vary with \(\gamma \epsilon\). Such shift-dependent RHS situations arise naturally in acoustics problems, but also arise when the system (32) for fixed \(i, j\) denotes a correction equation: that is, when the right-hand side denotes the initial residual \(r_j^{(\epsilon)}\).

There are iterative methods that have been tailored to accommodate multiple shifts, and we discuss those briefly here first. Then we move on to discussing impediments to adding recycling on top of these shifted system solvers in Section 7.1.1 and methods that are used to overcome these obstacles in Section 7.2.

### Iterative Methods Tailored to Shifted Systems

For Arnoldi-based methods for large non-Hermitian matrices, it is likely that restarting will be necessary. Enforcing a (Petrov-) Galerkin condition for each shifted system does not guarantee that residuals remain collinear. At the restart stage, then, we are possibly in the position of having to solve systems with multiple shifts, and shift dependent RHS, where the RHS now correspond to the current respective residuals. The necessary conditions for residuals to remain collinear at restart were characterized in \([114]\), Theorem 1. Methods such as the full orthogonalization method (FOM) \([112]\), conjugate gradients \([110,111]\) (which is a highly specialized implementation of FOM for HPD matrices), and bi-conjugate gradients (BiCG) \([111]\) maintain a natural residual collinearity. Other methods such as GMRES, MINRES, and QMR do not naturally maintain residual collinearity. Since QMR and MINRES use short-term recurrences, this was shown not to be a great obstacle \([112]\).

In \([111]\), a restarted GMRES algorithm to simultaneously solve a family of shifted systems was derived. The key is that the residual of only one system is minimized. The residuals for the other systems are then explicitly forced to be collinear to this minimized residual. This collinearity correction may not always exist, but it was shown in \([114]\) that if \(A\) has field of values in the right half-plane and the shifts are all positive, real numbers, then one can always enforce the residual collinearity.

An extension of BiCGStab(\(\epsilon\)) for shifted systems has also been proposed \([114]\). Shifted BiCGStab(\(\epsilon\)) works by alternating \(\epsilon\)-cycles of shifted BiCG (which naturally maintains residual collinearity) and of shifted GMRES (which enforces residual collinearity). As with shifted GMRES, shifted BiCGStab(\(\epsilon\)) retains the property that it will always be able to generate collinear residuals in the case that the shifts are all positive and the coefficient matrix \(A\) has field of values in the right half-plane.
7.1.1 Difficulties combining recycling with shifted system solvers

Combining the shifted GMRES method [114] with the GCRO-DR approach [113] was a part of the doctoral dissertation [115], and these results were extended and refined in [116]. In this work, it was shown that for general non-Hermitian coefficient matrices and augmentation subspaces, it is not possible to embed a shifted restarted GMRES within a subspace recycling framework as described in Section 4.1. An alternative is proposed, but its effectiveness decreases as the magnitude of the shift increases.

Essentially, for a given augmentation space $U$ and its image $C$, each shifted system must be projected as in Section 4.1 and the shifted restarted GMRES then is applied to the projected problems. This leads to three challenges: the projection of the initial residuals, the exploitation of possible shift invariance of the Krylov subspace generated by the projected coefficient matrix, and the enforcement of a residual collinearity condition at the end of each cycle. The correct initial residual projection was not fully treated until [106], and we will defer discussion thereof until Section 7.1.2. Under favorable circumstances in the case of optimal recycling methods for minimum residual Krylov subspace methods, it can be proven that a family of projected shifted matrices still generate the same Krylov subspace. This fact has been used in works as early as [66].

Proposition 1. [116, Proposition 3.1] Let $Q$ be the orthogonal projector onto $C$. Then for any $v \in C^\perp$ we have that

$$K_j ((I - Q) A, v) = K_j ((I - Q) (A + \gamma I), v).$$

This projected operator shift invariance was later extended to Sylvester operators in [116]. What Proposition 1 shows is that when restarting is not required, one can generate one augmented Krylov subspace $U + K_j ((I - Q) A, r_0)$ and compute minimum residual corrections for each shifted system therefrom. This was used in [66], since the problems were real symmetric; and as was shown, it is compatible in the real case with complex shifts.

The question that remains is whether such a method can be extended to the non-Hermitian case when restarts are required. Ideally, as in [114], for one system we would compute the minimum residual correction, and for all other systems corrections would be computed that give residuals collinear to the minimized residual. However, it was shown in [116, Theorem 1] that this is not generally possible. However, in certain situations, the collinear residual was shown to exist. For example, if $U = C$ is an invariant subspace, then it is possible to compute collinear residuals as in [114]. More generally, if

$$U + K_j ((I - Q) A, r_0) \subset C + K_{j+1} ((I - Q) A, r_0),$$

then it is possible to enforce residual collinearity. Indeed the shifted GMRES-DR method [116] takes advantage of this relationship, as Morgan previously proved that a Krylov subspace augmented with harmonic Ritz vectors satisfies (34) [25]. Absent this property, however, enforcing shifted residuals to be collinear to the minimized one is not possible [116].

7.1.2 Effective recycling strategies for shifted systems

The problems discussed in (7.1.1) are impediments to combining these two technologies, but a number of strategies have been proposed which either overcome or work around the problems discussed in Section 7.1.1 and for scalar shifted linear systems, there are certain circumstances for which we can take advantage of the shift invariance property and still augment. We note again that these methods treat the case where the right-hand sides/residuals do differ at some point. Even if we begin in the setting that we have the same right-hand side for all shifts, we are dealing with methods which destroy that structure, leaving residuals which are either collinear but not equal or which have no relationship to one another.

GMRES-DR and FOM-DR

As has been mentioned, for solving a single linear system with non-Hermitian coefficient matrix using an Arnoldi-based restarting approach, shifted versions of GMRES-DR and FOM-DR have been proposed and have shown to be effective [82]. Both unshifted algorithms work by retaining some harmonic Ritz or Ritz vectors, respectively, to augment the Krylov subspace generated in the next cycle. It is shown in [23] that in each case, that the resulting space is in actuality a Krylov subspace with a different starting vector. In the augmentation language used in this survey, these appended vectors span the subspace $U'$, and the space $U'$ and $C = \mathbf{A} U'$ satisfy Equation (34). Thus, in the case of GMRES-DR, one can enforce residual collinearity, as in the manner of [114]. For FOM-DR, one has the natural collinearity through enforcement of the Galerkin condition due to [114, Theorem 1].

Direct projection

In [116], it was shown that one cannot generally enforce shifted residuals to be collinear with the minimized residual of the seed system when minimizing over an augmented Krylov subspace. So, if looking for collinear residuals is not a workable solution, one can instead simply exploit the shifted system structure directly. In [21], it is proposed to perform a minimum residual
projection for all shifted systems over the (augmented) Krylov subspace generated by the base matrix and right-hand side. This was shown to be effective in some circumstances. For non-augmented Krylov subspaces, one could still exploit the shifted system structure such that the methods was still reasonably efficient, but the version of this method for GCRO-DR is still quite costly, in terms of extra floating-point calculations one must carry out for the shifted systems.

Sylvester equation interpretation
It has been observed that a family of shifted systems can instead be interpreted as the Sylvester equations
\[
A \begin{bmatrix} x_1 & x_2 & \cdots & x_s \end{bmatrix} + \begin{bmatrix} x_1 & x_2 & \cdots & x_s \end{bmatrix} \begin{bmatrix} y_1 & y_2 & \cdots & y_s \end{bmatrix} \begin{bmatrix} b^{(r)} & b^{(r)} & \cdots & b^{(r)} \end{bmatrix} = 0.
\]
Simoncini showed that one could approximate the solution to this Sylvester equation by generating the block Krylov subspace \(K_j(A, R_0)\) generated by the block initial residual \(R_0 = B - AX_0 - X_0D\). One can apply a GMRES minimization over this space simultaneously for all shifted systems without consideration of residual collinearity or any relationship between residuals. Thus, it was observed in [116] that building a subspace recycling method on top of this minimization process suffers from none of the restrictions that were seen in [106].

This method also allows one to take advantage of theory presented in [107], where it was shown that any parameter-dependent family of linear systems has a family of solutions well-approximated in a subspace of small dimension. The smallness of the dimension has an upper bound depending on how smoothly the right-hand side and linear system depend on the parameter.

In [106], an experiment is set up such that a family of shifted systems (i.e., \(A + \gamma I\) depends linearly on \(\gamma\)) have right-hand sides \(b^{(r)}\) which have \(C^\infty\) dependence on \(\gamma\). A few of the systems are solved using standard methods. These solutions span a recycling subspace used to rapidly solve all other systems. This structure can be exploited more generally in the context of recycling; cf. Section 7.5.

What if the residuals are collinear? If the RHS do not depend on the shifts, we can use the strategies employed in Section 7.2. If the residuals are collinear, one can use, e.g., the shifted GMRES method [114], though this cannot take advantage of recycling. Regardless, the Sylvester framework is a viable option. If there is no recycled subspace, one can begin by applying a cycle of GMRES to all shifted systems, generating a single Krylov subspace using the shift invariance, since residuals are collinear. Applying the GMRES minimization to each shifted system renders the residuals non-collinear, and we are then in the general setting and can apply the Sylvester equation strategy. If there is an initial recycled subspace, one applies the Sylvester equation strategy immediately, as this will destroy residual collinearity anyway.

7.2 Sequences of shifted systems with shift independent RHS
During the course of solving the optimization problem in image reconstruction from diffuse optical tomographic data, the authors of [54] encounter sequences of shifted linear systems of multiple right-hand sides (MRHS) [32] where the RHS do not depend on the shift, and where the non-zero shifts are pure imaginary (i.e., \(\gamma_r = i \omega_r\)):
\[
(A^{(i)} + \gamma \ell I)x^{(\ell, i, j)} = b^{(j)}, \quad \gamma \geq 0, j = 1, \ldots, j_s; i = 1, \ldots, i_s; \ell = 1, \ldots, L,
\]
where \(\gamma_1 = 0\). The approach can be readily adapted to handle in the case that the shift is real or complex. In their application, \(A^{(i)}\) are real and symmetric, though it is possible to extend the idea to non-symmetric matrices. Importantly, right-hand sides do not change as \(i\) changes, and are not a function of shift \(\ell\).

No shifts, Multiple RHS
The contributions contained in the 2006 paper [54] include recycling that takes advantage of similarities of the systems across all three indices, tailored in part to the optimization process. That is, for a given right-hand side, the recycle space consists of the shared recycling basis of approximate eigenvectors, augmented by a very small number of recent, prior solutions for that right-hand side, the idea of which prior solutions to include depends on where the solve occurs in the optimization process.

5In order to generalize to non-symmetric \(A^{(i)}\), the MINRES solver would need to be replaced with a GMRES solver. If restarts are necessary, then it may be necessary to incorporate components from the previous section as then intermediate residuals would depend on shift value.
Including Multiple Shifts

To describe their approach for the non-zero shifts we focus on a fixed right-hand side and drop the dependence on \(i\) and \(j\). Let \(U\) denote the recycle space for the current \(i, j\). Then the recycling recurrence gives

\[
AV_m = CB_m + V_{m+1}T_m, \quad B_m := CTAV_m,
\]

and as before, an optimal solution is sought in \(\text{Range}(\{V_m, U\})\). After some manipulation, the least squares problem for the solution ultimately leads to the projected problem

\[
\begin{align*}
\min_{y, z} \left\| \begin{bmatrix} \varepsilon e_1 \\ CTb \\ 0 \end{bmatrix} - \begin{bmatrix} T_m + \gamma_r L_m & \gamma V_{m+1}T_m \\ B_m & \gamma_r CTU \\ 0 & 0 \end{bmatrix} \begin{bmatrix} y \\ z \end{bmatrix} \right\|_2 & \quad \text{or} \quad \min_{y, z} \left\| \begin{bmatrix} C b \\ \varepsilon e_1 \\ 0 \end{bmatrix} - \begin{bmatrix} I + \gamma_r (CTU) \\ B_m \\ \gamma_r N \end{bmatrix} \begin{bmatrix} y \\ z \end{bmatrix} \right\|_2
\end{align*}
\]

where \(N\) arises from orthogonalizing \(U\) against \(\{V_{m+1}, C\}\) and the solution is \(x = V_m y + U z\). Numerical difficulties are observed if \(\text{Range}(U)\) is very close to an invariant subspace of \(A\). The problem on the right is preferred when \(\text{Range}(U)\) is expected to be very close to an invariant subspace of \(A\), or when storage is at a premium, since in the this case, \(V_m y\) and \(B_m y\) can be computed via short term recurrences when \(A\) is symmetric, avoiding the storage of the \(V_m\).

7.3 Inner-outer Recycling

The concept of inner-outer recycling for systems of the form \(Ax = b\) for sequences for systems with pure imaginary shift and shift-independent MRHS was first developed in \cite{117} in the context of producing a global basis necessary for reduced order modeling in the diffuse optical tomographic imaging problem. As in the previous section, the \(A^{(i)}\) are real symmetric and the shifts are pure imaginary. To understand how the inner-outer recycling is useful in context, consider that the current global basis for creating a reduced order model is the same as the master recycle space, \(\text{Range}(U)\). After solving the next set of systems in the sequence, columns may be appended to the global basis. Once the global basis is sufficient, system solves for future \(i\) are replaced by system solves with \(U^TA^{(i)}U\), called the reduced order model (ROM), which should have a significantly smaller dimension than that of \(A^{(i)}\). Going forward, the optimization relies on solves with the ROM, so optimization steps are much cheaper.

Again, assume \(i\) is fixed and first, assume \(\gamma = 0\). Given that \(AU = C, CT = I\), the optimal solution in \(\text{Range}(U)\) is \(z = UCb^{(j)}\), and the initial residual is \((I - CC^T)b^{(j)}\). In the traditional recycling approach, the search space would expanded by forming a basis for the Krylov subspace generated by the projected matrix \((I - CC^T)A\) and initial residual, but unfortunately the number of columns in \(U\) that are needed for a good ROM, orthogonalization would become too costly.

The authors of \cite{117} observed that to enhance the global basis, one need not find an approximation to \(x^{(i)}\) directly, but rather to add information that is not already reconstructible from \(\text{Range}(U)\). For each \(j\), there is a correction equation

\[
Ag^{(j)} = r^{(j)}, \quad g^{(j)} := x^{(j)} - UCb^{(j)}, \quad (36)
\]

for which the authors look for the optimal \(g^{(j)}\) restricted to a suitable subspace \(S^{(j)}\). Their idea is to define a local recycling space \(\text{Range}(U^{(j)}) \subset \text{Range}(U)\) and use it to apply recycling MINRES to solve Equation \(36\). It differs from the method in the previous section in that: a) here, the initial solution is computed over a larger, single, master subspace while in the previous approach, they are doing standard recycling with a different recycle space for each different right hand side, although those different spaces do intersect; b) the inner recycling step is a standard recycling iterative solver, but over the correction equation for the initial solution that was computed on the larger, master recycle space. Since \(\text{Range}(U^{(j)}) \subset \text{Range}(U)\) is maintained, a short-term recurrence update is also possible.

Updating Across Shifted Systems

The global basis matrix must provide a suitable reduced transfer function for the 0 as well as the pure imaginary shifts \(\gamma_r\). The authors observed that in their application, magnitude of the shifts are small enough that the real parts of the solutions to the shifted systems are not far (in a relative sense) from the corresponding solutions to the 0 shift case. Thus, in \cite{117}, they initialize the master recycle space \(U\) (and all the local recycle spaces \(U^{(j)}\)) with the solutions to the 0 frequency systems for \(k = 1\). They also augment \(U\) (and \(U^{(j)}\)) by the imaginary parts of the solutions to the corresponding imaginary shifted systems for \(k = 1\). This ensures that \(U\) and all the \(U^{(j)}\) remain real for all \(k\).

For a \(k \geq 2\), the non-shifted systems for \(j = 1, \ldots, j_k\) are first solved using the inner-outer recycling described above. Then, the non-zero shifted systems are updated. Assuming \(x^{(i)} \approx Uq^{(i)}\), Petrov-Galerkin projection is applied so that \(C^*r^{(i)} = 0\),
giving the solution estimate for the \( \ell \)'th shift and \( j \)th right-hand side as
\[
x^{(\ell,j)} \approx U \left( I + \gamma \sigma_j C^* U \right)^{-1} C^* b^{(j)}, \quad \text{where} \quad C^* U = U^* A U.
\] (37)

No additional correction system is solved for any shifted system; the corrections are found only for the non-shifted systems for all right-hand sides, as before. It should be noted that the elements of the work in [106] were inspired by this strategy.

### 7.4 A family of matrices \( \{A + \gamma \epsilon E\}^L_{\epsilon=1}, E \neq I \)

**Inner-Outer recycling over shifts**

In [118], a similar idea of maintaining an outer, master subspace across all shifts, and local, shift-specific recycle spaces is introduced. The method assumes symmetric \( A^{(i)} \), but the shift matrix \( E \) need only be real, and the shifts can be anything. We describe the procedure here for a single RHS, but details for MRHS can be found in [118]. The master subspace, \( U \), is initially seeded with all the solutions across all the shifts for the first system (\( i = 1 \)), as well as approximate invariant subspace information for a fixed shift value (for simplicity, assume this is for \( \gamma = 0 \)). At step \( i + 1 \), the columns of \( C \) provide an orthonormal basis for Range(\( A^{(i+1)} U \)).

Then, initial guesses to the solutions across all shifts are obtained over \( U \) via a Petrov-Galerkin constraint on residuals. If the corresponding residual \( r^{(\ell)} \) to the \( \ell \)'th shift is not small enough, \( U^{(\ell)} \) is selected such that Range(\( U^{(\ell)} \)) \( \subseteq \) Range(\( U \)). The orthonormal columns of \( C^{(\ell)} \) provide a basis for Range((\( A^{(i+1)} + \gamma \epsilon E \))U^{(\ell)}). The solution to the residual correction equation is sought from Range(\( U^{(\ell)} V^{\ell} \)) where \( V^{\ell} \) is the basis for the Krylov subspace generated by \( (I - C^{(\ell)} (C^{(\ell)})^T)(A^{(i+1)} + \gamma \epsilon E) \) and vector \( (I - C^{(\ell)} (C^{(\ell)})^T) \eta^{(\ell)} \). It is important to note that \( C \) is a basis for the range of \( U \) under the fixed shift matrix (in the present discussion, \( \gamma = 0 \)), but while \( U^{(\ell)} \subseteq U \), \( C^{(\ell)} \) is a basis for range of \( U^{(\ell)} \) under \( (A^{(i+1)} + \gamma \epsilon E) \).

**Double Shifts, Single RHS**

In [119], the authors consider an application in hyperspectral DOT, but the system matrix \( A \) remains unchanged and recycling is only over the wavelengths (i.e. shifts are real-valued). Here, the system matrices are a small perturbation to systems shifted by the identity, \( (A + \gamma \epsilon I + \mu \epsilon E) \) and with a single RHS. It is also assumed \( \|E\|_2 \ll \|A\|_2 \). Thus, the shift invariance property is first used to generate initial guesses to solutions, ignoring \( E \). Recycling is then used on each individual residual correction equation.

While the general recycling strategy follows [17], it differs in the way that the recycle and range spaces are updated. This is possible because \( A_{\epsilon} := A + \sigma \epsilon I + \mu \epsilon E = A_{\epsilon-1} + \Delta_{\epsilon} \), where \( \Delta_{\epsilon} = (\sigma \epsilon - \sigma_{\epsilon-1}) I + (\mu \epsilon - \mu_{\epsilon-1}) E \). So, once the \( U \) and \( C \) for \( A \) are known, finding \( C_{\epsilon} \) for \( A_{\epsilon} \) can be done independently across \( \epsilon \) and parallelized, so all the shifted systems can be handled independently.

**Other Methods**

There have been other iterative approaches proposed in the literature that deal with shifted systems. In some of these, such as [120], the focus is on preconditioning to convert systems to those for which shift-invariance can be leveraged, but subspace recycling is not explicitly used and therefore we do not review that literature here. Other literature comes closer in spirit: the authors of [121] propose a deflation based Lanczos approach for the symmetric parameterized systems whose matrices correspond to a frequency response function. The method is similar in the sense of projecting out a set of (in this case, generalized) eigenvectors, so some form of deflation that leads to faster convergence. This can be done for multiple shifts. However, since this is based on generalized eigenvectors, this does not give standard spectral deflation in the sense described above, so we do not consider it further here.

### 7.5 General parameterized families with continuous parameter dependence

We discussed in Section 7.1.2 if the right-hand sides exhibit sufficiently smooth dependence on the shift for all shifts in some interval, then the solutions associated to all shifts in this interval can be approximated to machine accuracy in a small subspace \( S \) which has a dimension dependent on the smoothness of the dependence on the shift. This theory was developed in [107], and it applies more generally to parameter-dependent linear systems of the form
\[
A(s)x(s) = b(s) \quad s \in \mathbb{C}.
\] (38)

If dependence of \( A(s) \) and \( b(s) \) is sufficiently smooth for all \( s \) in some neighborhood \( \Omega \subset \mathbb{C} \), then the associated solutions all exist in a small subspace \( S \) of dimension \( d \), which depends on the smoothness of the dependence. In [107], upper bounds for \( d \) are given in terms of the smoothness of this dependence on \( s \). Thus, one can propose a recycling algorithm to take advantage of this
theory. For \((38)\), if we have determined \(d < d_M\), then we can build a recycled subspace by choosing \(\{s_1, s_2, \ldots, s_{d_M}\} \subseteq \Omega\) in the neighborhood and use any method to solve the linear systems associated to these shifts. The solutions \(\{x(s_1), x(s_2), \ldots, x(s_{d_M})\}\) form the recycled subspace which can be used to solve all systems for other \(s \in \Omega\).

8 USES IN PRACTICAL APPLICATIONS

Large Scale Software Libraries
Recycling solvers have been implemented in major software/solver libraries, most notably in PETSc \([122–126]\), see \([127]\) for a discussion on performance and applications in elasticity and electromagnetics, Trilinos \([128–130]\), and the DLR-TAU library from the German Aerospace Center, see \([131,132]\), which also detail several challenging applications in CFD.

Computational Scientific and Engineering Applications
Recycling solvers have been used in a wide range of applications, ranging from calculations for fundamental problems in computational physics to large-scale astrophysical simulations, tomography and medical imaging, and many applications in computational engineering, sometimes with modifications that serve a specific application. Recycling solvers and closely related approaches have been used in Lattice Quantum Chromodynamics \([46,82,133–135]\), in particular, \([134]\) mentions that recycling is important for handling physical regimes with very small eigenvalues. Many problems in design involve sequences of slowly changing linear system, for which recycling is highly efficient, e.g., in topology optimization and other structural optimization problems \([55,108,136–138]\), and aerodynamic shape optimization \([78,139]\). Recycling has also been used to compute reduced order models (for a range of applications) \([58,91,117,140,141]\). Another important area is nonlinear optimization, such as nonlinear least-squares, e.g., in tomography \([56,66,117,119]\) and blind deconvolution \([142]\), Many application arise in engineering, such as computational fluid dynamics and nonlinear structural problems \([75,100,131,132,143–145]\), acoustics \([121,146]\), and problems from electromagnetics and electrical circuits \([45,127,147,150]\). Recycling has also been used to compute reduced order models (for a range of applications) \([58,91,117,140,141]\). Another important area is nonlinear optimization, such as nonlinear least-squares, e.g., in tomography \([56,66,117,119]\) and blind deconvolution \([142]\), Many application arise in engineering, such as computational fluid dynamics and nonlinear structural problems \([75,100,131,132,143–145]\), acoustics \([121,146]\), and problems from electromagnetics and electrical circuits \([45,127,147,150]\). Recycling has also been used to compute reduced order models (for a range of applications) \([58,91,117,140,141]\).

9 OUTLOOK AND FUTURE WORK

There are yet many interesting extensions of the work mentioned above. One important area is a better understanding of what type of subspaces to recycle for fast convergence and how to compute such subspaces efficiently, especially in the context of particular applications and in terms of what can be learned from previous iterations/linear systems. A second area is convergence theory related to various recycle approaches, particularly, biorthogonality-based recycling approaches. Third, further work is needed to investigate how to best combine recycling and preconditioning and to determine whether or not the the framework outlined here can help in this respect. Finally, we note that there are classes of problems – for example, discrete ill-posed problems – where the convergence needs and problem properties are different; thus different ways of thinking about recycling in this context might be needed.

ACKNOWLEDGMENTS

The authors wish to thank the ANLA activity group for inviting us to write on this topic. The work by Eric de Sturler was supported in part by the grant NSF DMS 1720305; the work by Misha Kilmer was supported in part by the grant NSF DMS-1720291.
