Abstract:
The high accuracy envisaged for future measurements of W-boson production at hadron colliders has to be matched by precise theoretical predictions. We study the impact of electroweak radiative corrections on W-boson production cross sections and differential distributions at the Tevatron and at the LHC. In particular, we include photon-induced processes, which contribute at $O(\alpha)$, and leading radiative corrections beyond $O(\alpha)$ in the high-energy Sudakov regime and from multi-photon final-state radiation. We furthermore present the calculation of the complete supersymmetric next-to-leading-order electroweak and QCD corrections to W-boson hadroproduction within the MSSM. The supersymmetric corrections turn out to be negligible in the vicinity of the W resonance in general, reaching the percent level only at high lepton transverse momentum and for specific choices of the supersymmetric parameters.
1 Introduction

The Drell–Yan-like production of W bosons,

\[ pp/\bar{p}p \to W \to l\nu_l X, \]  

(1.1)
is one of the cleanest hadron collider processes with a large cross section at the Tevatron and at the LHC. Measurements near the W resonance allow for a precise determination of the W-boson mass and yield valuable information on the parton structure of the proton. Above resonance, the off-shell and high-energy tails of appropriate distributions are sensitive to the W width and offer the possibility to search for additional charged gauge bosons \( W' \). (See e.g. Refs. [1, 2] and references therein.)

The high experimental precision envisaged at the Tevatron Run II and specifically at the LHC has to be matched by precise theoretical predictions including QCD and electroweak radiative corrections. The QCD corrections are completely known up to next-to-next-to-leading order (NNLO) [3] and up to \( N_3\)LO in the soft-plus-virtual approximation [4], with a remaining theoretical error for inclusive cross sections at the percent level or lower. The next-to-leading-order (NLO) QCD corrections have been matched with parton showers [5] and combined with a summation of soft gluon radiation (see e.g. Ref. [6]), which is particularly important to reliably predict the W transverse-momentum distribution. A theoretical study of the QCD uncertainties in the determination of the W cross section at hadron colliders has been presented in Ref. [7].

In this article we mainly focus on the electroweak corrections. Given, for example, the anticipated experimental accuracy in the W-boson mass measurement of \( 10^{-20} \) MeV at the LHC, the inclusion of electroweak corrections beyond final-state radiation is mandatory as their omission would induce a systematic error in the \( M_W \) determination of \( \mathcal{O}(10 \text{ MeV}) \) (see e.g. Ref. [1]). The complete NLO \( \mathcal{O}(\alpha) \) corrections to the parton process \( q\bar{q}' \to W \to l\nu_l \) have been calculated by several groups [8–11]. A tuned comparison of cross sections and differential distributions has shown good agreement between the various calculations [1, 12]. Photon-induced processes \( \gamma q \to l\nu_l q' \), which also contribute at \( \mathcal{O}(\alpha) \), have been computed recently in Refs. [13, 14].

The particular importance of final-state photon radiation for the W-boson mass determination demands a treatment that goes beyond \( \mathcal{O}(\alpha) \). Such multi-photon effects have been studied in Refs. [15, 16] and matched to the NLO \( \mathcal{O}(\alpha) \) calculation in Ref. [11]. First steps towards combining QCD and electroweak higher-order effects have been taken in Ref. [17]. We note that the \( \mathcal{O}(\alpha) \) corrections to hadronic production of on-shell W bosons at large transverse momenta, \( pp/\bar{p}p \to W + \text{jet} \), have recently been presented in Ref. [18] for the Standard Model (SM) and in Ref. [19] in the minimal supersymmetric Standard Model (MSSM). For related work on electroweak corrections to Z-boson hadroproduction we refer to Refs. [1, 12] and further references therein.

In this paper we improve on our previous \( \mathcal{O}(\alpha) \) calculation [9] for \( pp/\bar{p}p \to W \to l\nu_l X \) by including photon-induced processes and multi-photon final-state radiation in the structure-function approach. We also discuss the impact of leading electroweak effects beyond \( \mathcal{O}(\alpha) \), specifically the Sudakov logarithms that arise in the high-energy regime, and present the calculation of the complete supersymmetric \( \mathcal{O}(\alpha) \) electroweak and \( \mathcal{O}(\alpha_s) \) strong corrections within the MSSM. The purpose of the MSSM calculation is to establish that the impact of virtual supersymmetric particles on the cross section prediction is small and does not spoil the status of single-W-boson production as one of the cleanest SM candles at hadron colliders.

The paper is organized as follows. In Section 2.1 we briefly summarize the calculation of the complete \( \mathcal{O}(\alpha) \) corrections as originally presented in Ref. [9]. In the following sections, we describe the inclusion of leading electroweak effects beyond \( \mathcal{O}(\alpha) \), the calculation of the
photon-induced processes, and the summation of multiple emission of collinear photons off the final-state lepton. Numerical results for W-boson production at the Tevatron and the LHC including the complete $\mathcal{O}(\alpha)$ and $\mathcal{O}(\alpha_s)$ NLO corrections and the higher-order Sudakov and photon radiation effects are presented in Section 2.6. There, we also compare our results on multi-photon final-state radiation in the structure-function approach with results based on the parton-shower approach \cite{1}. In Section 3 we describe the calculation of the MSSM corrections and discuss their numerical impact on the W cross section and distributions. We conclude in Section 4. Finally, the Appendix provides details on the scenarios of the supersymmetric models under consideration.

2 Higher-order electroweak effects

In the next section, we briefly review the calculation of the complete $\mathcal{O}(\alpha)$ corrections to the parton process $qg' \rightarrow W \rightarrow l\nu_l$ presented in Ref. \cite{9} which is now augmented by an extension of the dipole subtraction method \cite{20} that allows us to calculate non-collinear-safe observables also within the subtraction approach. In the subsequent sections, we then discuss the leading electroweak effects and the choice of couplings before we present those parts of the calculation that are new and that have not been discussed in Ref. \cite{9}. We present our results for the specific case of $W^+$ production, $pp/\bar{p}p \rightarrow W^+ \rightarrow l^+\nu_lX$.

2.1 Electroweak $\mathcal{O}(\alpha)$ corrections

We consider the parton process

\begin{equation}
q_u(p_u) + \bar{d}(p_d) \rightarrow u_l(k_u) + l^+(k_l) \ [+\gamma(k)] ,
\end{equation}

where $u$ and $d$ generically denote the light up- and down-type quarks, $u = u, c$ and $d = d, s$. The lepton $l$ represents $l = e, \mu$. The momenta of the particles are given in brackets, and the Mandelstam variables are given by

\begin{align}
\hat{s} &= (p_u + p_d)^2 , \quad \hat{t} = (p_d - k_l)^2 , \quad \hat{u} = (p_u - k_l)^2.
\end{align}

We neglect the fermion masses $m_u, m_d, m_l$ whenever possible, i.e. we keep these masses only as regulators in the logarithmic mass singularities originating from collinear photon emission or exchange. In lowest order the scattering amplitude reads

\begin{equation}
\mathcal{M}_0 = \frac{e^2 V_{ud}^*}{2s_W^2} [\bar{u}_d \gamma^\mu \omega_- u_u] \frac{1}{s - M_W^2 + iM_W\Gamma_W(\hat{s})} [\bar{u}_\nu_l \gamma_\mu \omega_- v_l] ,
\end{equation}

with an obvious notation for the Dirac spinors $\bar{v}_d$, etc., and the left-handed chirality projector $\omega_- = \frac{1}{2}(1 - \gamma_5)$. The electric unit charge is denoted by $e$, the weak mixing angle is fixed by the ratio $e_W^2 = 1 - s_W^2 = M_W^2/M_Z^2$ of the W- and Z-boson masses $M_W$ and $M_Z$, and $V_{ud}$ is the CKM matrix element for the $ud$ transition. The different choices for the fine-structure constant $\alpha = e^2/(4\pi)$ in the squared matrix element are discussed below.

Strictly speaking, Eq. (2.3) already goes beyond lowest order, since the W-boson width $\Gamma_W(\hat{s})$ results from the Dyson summation of W self-energy insertions. Renormalizing the W mass and width in the on-shell scheme, the Dyson summation directly leads to a running width, i.e.

\begin{equation}
\Gamma_W(\hat{s})_{\text{run}} = \Gamma_W \frac{\hat{s}}{M_W^2}.
\end{equation}
On the other hand, defining W mass and width from the location of the pole of the W propagator (with momentum transfer \( p \)) in the complex \( p^2 \) plane, naturally leads to a constant width, i.e.

\[
\Gamma_W(\hat{s})|_{\text{const}} = \Gamma_W. \tag{2.5}
\]

In this work, we employ the fixed-width approach (2.5). This has to be kept in mind when using the results in precision determinations of the W-boson mass from the W resonance.

The virtual one-loop corrections comprise contributions of the transverse part of the W self-energy \( \Sigma_W^T \), corrections to the two \( W du \) and \( W \nu l \) vertices, box diagrams, and counterterms. Our calculation of these corrections is described in Ref. [9] in detail. In particular, the complete expressions for the vertex and box corrections are provided in the Appendix of that reference. For this paper we recalculated the one-loop effects employing the packages \texttt{FeynArts} [21], \texttt{FormCalc}, and \texttt{LoopTools} [22], supplemented by the loop integrals with singularities on the W resonance, which are discussed below. In both calculations, ultraviolet divergences are treated in dimensional regularization, and the infrared (IR) singularity is regularized by an infinitesimal photon mass \( m_\gamma \). The actual calculation is performed in ’t Hooft–Feynman gauge using on-shell renormalization.

The complete one-loop amplitude \( \mathcal{M}_1 \) can be expressed in terms of a correction factor \( \delta^{\text{virt}} \) times the lowest-order matrix element,

\[
\mathcal{M}_1 = \delta^{\text{virt}} \mathcal{M}_0. \tag{2.6}
\]

Thus, in \( \mathcal{O}(\alpha) \) the squared matrix element reads

\[
|\mathcal{M}_0 + \mathcal{M}_1|^2 = (1 + 2 \Re \{ \delta^{\text{virt}} \}) |\mathcal{M}_0|^2 + \ldots, \tag{2.7}
\]

so that the Breit–Wigner factors are completely contained in the lowest-order factor \( |\mathcal{M}_0|^2 \). Note that the Dyson-summed imaginary part of the W self-energy, which appears as \( \Gamma_W(\hat{s}) \) in \( \mathcal{M}_0 \), is not double-counted, since only the real part of \( \Sigma_W^T \) enters \( \Re \{ \delta^{\text{virt}} \} \) in \( \mathcal{O}(\alpha) \). Despite the separation of the resonance pole \( (\hat{s} - M_W^2)^{-1} \) from the correction factor \( \delta^{\text{virt}} \) in (2.6), \( \delta^{\text{virt}} \) still contains logarithms \( \ln(\hat{s} - M_W^2 + i\epsilon) \) that are singular on resonance. Since these singularities would be cured by a Dyson summation of the W self-energy inside the loop diagrams, we substitute

\[
\ln(\hat{s} - M_W^2 + i\epsilon) \rightarrow \ln(\hat{s} - M_W^2 + iM_W\Gamma_W) \tag{2.8}
\]

with a fixed width everywhere. The substitution (2.8) does not disturb the gauge-invariance properties of the one-loop amplitude \( \mathcal{M}_1 \).

In Ref. [9] (Section 2.2) three different input-parameter schemes have been specified for the choice of the electromagnetic coupling constant \( \alpha \) that is taken as SM input together with the particle masses. According to the choice of \( \alpha \), the schemes are called “\( \alpha(0) \)”, “\( \alpha(M_Z^2) \)”, and “\( G_{\mu} \)” schemes, where \( \alpha \) is set to \( \alpha_{G_{\mu}} = \sqrt{2} G_{\mu} M_W^2 (1 - M_W^2/M_Z^2) / \pi \) in the \( G_{\mu} \) scheme. In the \( \alpha(0) \) scheme, the charge renormalization constant \( \delta Z_e \) in the counterterm \( \delta_{W f f'}^{\text{ct}} \) of the \( W f f' \) vertex contains logarithms of the light-fermion masses which are related to the running of the electromagnetic coupling \( \alpha(Q^2) \) from \( Q = 0 \) to a high-energy scale. In the \( \alpha(M_Z^2) \) scheme the counterterm changes to

\[
\delta_{W f f'}^{\text{ct}}(M_Z^2) = \delta_{W f f'}^{\text{ct}}(0) - \frac{1}{2} \Delta \alpha(M_Z^2), \tag{2.9}
\]

where

\[
\Delta \alpha(Q^2) = \Pi_{f \neq t}^{A_4}(0) - \Re \{ \Pi_{f \neq t}^{A_4}(Q^2) \}, \tag{2.10}
\]
with $\Pi_{\alpha \neq t} A^4$ denoting the photonic vacuum polarization induced by all fermions other than the top quark. In contrast to the $\alpha(0)$ scheme the counterterm $\delta_{Wff'}^{ct}\big|_{\alpha(M_Z^2)}$ does not involve light quark masses, i.e. the large logarithmic corrections are absorbed in the lowest order by using the appropriate numerical value for $\alpha(M_Z^2)$. In the $G_\mu$ scheme, the transition from $\alpha(0)$ to $G_\mu$ is ruled by the quantity $\Delta r$ which is deduced from muon decay,

$$\alpha_{G_\mu} = \frac{\sqrt{2} G_\mu M_W^2 s_W^2}{\pi} = \alpha(0)(1 + \Delta r) + O(\alpha^3). \quad (2.11)$$

Therefore, the counterterm $\delta_{Wff'}^{ct}$ reads

$$\delta_{Wff'}^{ct}\big|_{G_\mu} = \delta_{Wff'}^{ct}\big|_{\alpha(0)} - \frac{1}{2}\Delta r. \quad (2.12)$$

Since $\Delta \alpha(M_Z^2)$ is implicitly contained in $\Delta r$, the large fermion-mass logarithms are also absorbed in the lowest order in the $G_\mu$ scheme. The different input-parameter schemes are further discussed in Section 2.2.

The calculation of the real-photonic corrections is described in Ref. [9] in detail, both for a running and a fixed W-boson width. In order to respect electromagnetic gauge invariance, the coupling of the photon to W bosons has to be adapted when a running width is used. In the fixed-width approach, as used in this paper, no modification of couplings is needed.

The phase-space integral over the real-photonic matrix elements diverges in the soft and collinear regions logarithmically if the photon and fermion masses are set to zero. To properly combine the soft and collinear singularities with the corresponding virtual corrections three different methods are applied: two variants of phase-space slicing and the dipole subtraction method.

The dipole subtraction approach as formulated in Ref. [23] can only be applied for collinear-safe observables, i.e. observables for which selection cuts are blind to the distribution of momenta in collinear lepton–photon configurations. This can be achieved by “photon recombination”, where leptons and sufficiently collinear photons are treated as one quasi-particle (see also Section 2.6.2). For these observables the KLN theorem [24] guarantees that logarithms of the fermion masses are absent in the corrections. For muons in the final state it is, however, experimentally possible to separate collinear photons from the lepton, i.e. to observe so-called “bare” muons. Hence, the resulting cross sections are not collinear safe and the corresponding collinear singularities show up as logarithms of the small lepton masses.

In Ref. [9], only the slicing variants were able to deal with bare leptons, while the application of the subtraction approach was still restricted to collinear-safe observables. In this work, we employ an extension [20] of the subtraction formalism which allows one to calculate cross sections for bare leptons, i.e. cross sections defined without any photon recombination. The respective results of the slicing and subtraction methods are in good numerical agreement both for the inclusive and the bare muon case.

### 2.2 Leading electroweak effects and choice of couplings

As described in Ref. [9], the relative corrections in the various input-parameter schemes differ by constant contributions proportional to $\Delta \alpha(M_Z^2) \approx 6\%$ and $\Delta r \approx 3\%$, which quantify the running of the electromagnetic coupling from $Q^2 = 0$ to $Q^2 = M_Z^2$ for $\alpha(M_Z^2)$ and the radiative corrections to muon decay for the $G_\mu$ scheme, respectively. The bulk of $\Delta r$ is contained in $\Delta \alpha(M_Z^2) - c_W^2 \Delta \rho / s_W^2$, where $\Delta \rho \approx 1\%$ is the universal correction $\propto G_\mu m_t^2$ to the $\rho$ parameter.
The $G_\mu$ scheme is distinguished from the two other schemes because the corrections to charged-current four-fermion processes do not contain large contributions from $\Delta \alpha (M_Z^2)$ or $\Delta \rho$ anymore, i.e. these universal renormalization effects are completely absorbed into the leading-order (LO) amplitude. For the $O(\alpha)$ corrections this property has already been pointed out in Ref. [9], but it also holds at $O(\alpha^2)$. More precisely, in the $G_\mu$ scheme no contributions proportional to $\Delta \alpha (M_Z^2)^n$ (for any positive integer $n$), proportional to $\Delta \alpha (M_Z^2)\Delta \rho$, and proportional to $\Delta \rho^2$ appear. Based on the arguments given in Ref. [25] this feature was explicitly worked out in Ref. [26] (Section 3) for the related process of charged-current neutrino deep-inelastic scattering; these results obviously apply also to charged-current Drell–Yan scattering via crossing symmetry.

Before concluding that the theoretical uncertainties in the $G_\mu$ scheme from missing corrections beyond $O(\alpha)$ are smaller than in the two other schemes, we shall inspect other known universal dominant corrections at $O(\alpha)$. Besides the renormalization effects discussed above, the dominant $O(\alpha)$ corrections, up to moderate parton scattering energies, are due to final-state radiation off the charged lepton, at least for bare leptons where the enhancement by the large mass logarithm $\propto \alpha \ln m_l$ is present. The inclusion of these contributions beyond $O(\alpha)$, which are due to collinear multi-photon emission, is described in Section 2.5 below. Here we merely point out that the appropriate coupling constant $\alpha$ entering the relative correction is $\alpha(0)$, because it accounts for the emission of photons with $Q^2 = 0$. Thus, when adopting an input-parameter scheme other than the $\alpha(0)$ scheme, one should nevertheless use $\alpha(0)$ to multiply the dominating universal lepton-mass logarithms. Our specific implementation of this procedure is described in Section 2.5.

At high parton scattering energies and high transverse lepton momenta, electroweak corrections are dominated by soft and/or collinear gauge-boson exchange. The soft effects, known as Sudakov logarithms, induce powers of $\alpha \ln^2(s/M_W^2)$, with subleading soft/collinear contributions involving lower powers in the logarithm. In $O(\alpha)$, these enhanced electroweak effects drive the relative corrections to $\approx -30\%$ at lepton transverse momenta of about 1 TeV at the LHC [9]. It is therefore desirable to control this kind of corrections beyond $O(\alpha)$. We elaborate more on this issue in the next section. Here we just point out that among the considered input-parameter schemes the $G_\mu$ scheme should be appropriate to fix $\alpha$ for the leading high-energy logarithms, which are of weak origin.

Following the above arguments, we employ the $G_\mu$ scheme in this work, modified only by the change of $\alpha_{G_\mu}$ to $\alpha(0)$ in the leading part of final-state radiation. This procedure is expected to be most robust with respect to further corrections beyond $O(\alpha)$.

### 2.3 Leading weak corrections in the Sudakov regime

For single-W production at large lepton transverse momenta or W transverse masses, the parton kinematics is restricted to the Sudakov regime, characterized by large Mandelstam parameters $\hat{s}$, $\vert \hat{t} \vert, \vert \hat{u} \vert \gg M_W^2$. The structure of electroweak corrections beyond $O(\alpha)$ in this high-energy regime has been investigated in some detail by several groups in recent years (see e.g. Refs. [27–34] and references therein).

As described for example in Refs. [32, 34], the leading electroweak logarithmic corrections, which are enhanced by large factors $L = \ln(\hat{s}/M_W^2)$, can be divided into an SU(2)$\times$U(1)-symmetric part, an electromagnetic part, and a subleading part induced by the mass difference between W and Z bosons. The last part does not contribute to corrections $\propto (\alpha L^2)^n$ and is neglected in the following. The leading (Sudakov) logarithms $\propto (\alpha L^2)^n$ of electromagnetic origin cancel between virtual and real (soft) bremsstrahlung corrections; for the subleading logarithms such cancellations should strongly depend on the observable under consideration. The only source of leading logarithms is, thus, the symmetric electroweak (sew) part, which can be
characterized by comprising W bosons, Z bosons, and photons of a common mass $M_W$. Using this mass assignment, the one-loop correction $\delta_{\text{sew}}^{(1)}$ to the squared amplitude can be obtained by expanding the full result for the virtual correction $\delta_v$ (given in Appendix A of Ref. [9]) for large \( \hat{s}, |\hat{t}|, |\hat{u}| \gg M_W^2 \). The explicit result can be written as

$$\delta_{\text{sew}}^{(1)} = \frac{\alpha}{2\pi} \left\{ -L^2 C_{1,CC}^{\text{sew}} + L C_{1,CC}^{\text{ad}} \right\}$$

with factors

$$C_{1,CC}^{\text{sew}} = \frac{3}{2s_W^2} + \frac{Y_{\nu_L}^2 + Y_{\nu_L}^2}{4c_W^2}, \quad C_{1,CC}^{\text{ad}} = -\frac{2}{s_W^2} \ln\left( \frac{-\hat{t}}{\hat{s}} \right) + \frac{2}{c_W^2} Y_{\nu_L} Y_{\nu_L} \ln\left( \frac{-\hat{u}}{\hat{t}} \right),$$

which have been introduced in Section 8.4.2 of Ref. [34]. Here $Y_{\nu_L} = 1/3$ and $Y_{\nu_L} = -1$ are the weak hypercharges of the corresponding left-handed particles. In Eq. (2.13) we did not only include the leading Sudakov logarithms \( \propto \alpha L^2 \), but also the related “angular-dependent” contributions \( \propto \alpha L \ln(-\hat{t}/\hat{s}) \) or \( \propto \alpha L \ln(-\hat{u}/\hat{s}) \). Our explicit \( \mathcal{O}(\alpha) \) result is in agreement with the general results presented in Refs. [32, 34], where the corresponding corrections are also given at the two-loop level. These \( \mathcal{O}(\alpha^2) \) corrections can be obtained from the \( \mathcal{O}(\alpha) \) result by an appropriate exponentiation [30]. For the leading “sew” corrections (including \( \alpha^2 L^4, \alpha^2 L^3 \ln(-\hat{t}/\hat{s}), \) and \( \alpha^2 L^3 \ln(-\hat{u}/\hat{s}) \) terms) this exponentiation simply reads [34]

$$|\mathcal{M}|^2 \sim |\mathcal{M}_0|^2 \exp \left\{ \delta_{\text{sew}}^{(1)} \right\} = |\mathcal{M}_0|^2 \left( 1 + \delta_{\text{sew}}^{(1)} + \delta_{\text{sew}}^{(2)} + \ldots \right)$$

with

$$\delta_{\text{sew}}^{(2)} = \left( \frac{\alpha}{2\pi} \right)^2 \left\{ \frac{1}{2} L^4 (C_{1,CC}^{\text{sew}})^2 - L^3 C_{1,CC}^{\text{sew}} C_{1,CC}^{\text{ad}} \right\}.$$  \hfill (2.16)

However, in the case of neutral-current-induced fermion–antifermion scattering processes it was observed [33] that large cancellations take place between leading and subleading logarithms. In view of this uncertainty, we do not include the two-loop high-energy logarithms in our full predictions. Instead, we evaluate the leading two-loop part $\delta_{\text{sew}}^{(2)}$ as a measure of missing electroweak corrections beyond $\mathcal{O}(\alpha)$ in the high-energy Sudakov regime.

Moreover, since the electroweak high-energy logarithmic corrections are associated with virtual soft and/or collinear weak-boson or photon exchange, they all have counterparts in real weak-boson or photon emission processes which can partially cancel (but not completely, see Ref. [28]) the large negative corrections. To which extent the cancellation occurs depends on the experimental possibilities to separate final states with or without weak bosons or photons. This issue is discussed for example in Refs. [35, 36]. The numerical analysis presented in Ref. [36] demonstrates the effect of real weak-boson emission in the distributions in the transverse lepton momentum $p_{T,l}$ and in the transverse mass $M_{T,\nu l}$ of the W boson (as e.g. defined in Section 2.6.3 below). For $W^+$ production at the LHC, at $M_{T,\nu l} = 2\text{ TeV}$ the electroweak corrections are reduced from about $−26\%$ to $−23\%$ by weak-boson emission. At $p_{T,l} = 1\text{ TeV}$ the corresponding reduction from about $−28\%$ to $−17\%$ is much larger, however, the bulk of these emission effects is not due to soft/collinear weak-boson emission, but due to recoil effects in real $W^+W^−$ and $W^+Z$ production. This explicitly illustrates the sensitivity of weak-boson emission effects to the details of experimental event selection, in particular, how single-W production is separated from di-boson production.
2.4 Photon-induced processes

The $\mathcal{O}(\alpha)$ corrections to the parton cross section $q\bar{q}' \to W^+ \to l^+ \nu_l$ contain collinear singularities from photon radiation off the initial-state quarks which are absorbed by mass factorization [9–11]. For a complete and theoretically consistent analysis, the absorption of the $\mathcal{O}(\alpha)$ collinear singularities into quark distributions has to be complemented by both the inclusion of $\mathcal{O}(\alpha)$ corrections to the parton distribution functions (PDFs) and by the inclusion of the $\mathcal{O}(\alpha)$ partonic subprocesses $\gamma u \to l^+ \nu_l d$ and $\gamma d \to l^+ \nu_l \bar{u}$, which were first calculated in Ref. [13]. At the time of our previous study [9] a complete analysis of $\mathcal{O}(\alpha)$ corrections to PDFs, which involves $\mathcal{O}(\alpha)$ corrections to the DGLAP evolution and to the fit of experimental data, was not available. Meanwhile, the MRSTQED2004 [37] PDF parametrization, however, includes these corrections to the DGLAP evolution and to the fit of experimental data, was not available. Therefore, the MRSTQED2004 PDFs are defined for a complete and theoretically consistent analysis of $\mathcal{O}(\alpha)$ corrections to PDFs and provides a photon density within protons and antiprotons. It is thus now possible to perform a complete $\mathcal{O}(\alpha)$ analysis and to properly include the photon-induced subprocesses in the hadronic cross-section prediction.

The collinear photon splitting into two massless quarks in the subprocesses $\gamma u \to l^+ \nu_l d$ and $\gamma d \to l^+ \nu_l \bar{u}$ also leads to a mass singularity. As usual, this divergence is removed by mass factorization. Including both the divergences from collinear photon splitting and the divergence due to collinear photon emission from initial-state quarks in $q\bar{q}' \to l^+ \nu_l \gamma$, mass factorization implies a redefinition of the quark densities according to [26]

$$f_q(x) \to f_q(x, \mu_F) - \int_x^1 \frac{dz}{z} f_q \left( \frac{x}{z}, \mu_F \right) Q_q^2 \frac{\alpha}{2\pi} P_{q\gamma}(z) \ln \left( \frac{\mu_F^2}{m_q^2} \right) + C_{q\gamma}(z) \right\} - \int_x^1 \frac{dz}{z} f_q \left( \frac{x}{z}, \mu_F \right) 3 Q_q^2 \frac{\alpha}{2\pi} \left\{ \ln \left( \frac{\mu_F^2}{m_q^2} \right) P_{q\gamma}(z) + C_{q\gamma}(z) \right\}, \tag{2.17}$$

where $Q_q$ is the electric quark charge, $m_q$ is the small quark mass used as a regulator, and $\mu_F$ denotes the QED factorization scale which is identified with the QCD factorization scale. The factor 3 in the second line stems from the splitting of the photon into $q\bar{q}$ pairs of different color. Furthermore,

$$P_{q\gamma}(z) = \frac{1 + z^2}{1 - z}, \quad P_{q\gamma}(z) = z^2 + (1 - z)^2 \tag{2.18}$$

are the quark and photon splitting functions, respectively, and $C_{q\gamma}, C_{q\gamma}$ the coefficient functions specifying the factorization scheme. Following standard QCD terminology one distinguishes MS and DIS schemes defined by

$$C_{q\gamma}^{\text{MS}}(z) = C_{q\gamma}^{\text{DIS}}(z) = 0,$$

$$C_{q\gamma}^{\text{DIS}}(z) = \left[ P_{q\gamma}(z) \left( \ln \frac{1 - z}{z} - \frac{3}{4} \right) + \frac{9 + 5z}{4} \right]_+,$$

$$C_{q\gamma}^{\text{DIS}}(z) = P_{q\gamma}(z) \ln \frac{1 - z}{z} - 8z^2 + 8z - 1. \tag{2.19}$$

In our numerical analysis we employ the MRSTQED2004 parton distribution functions. Note that photon radiation off incoming quarks was ignored in the $F_2$ fit to HERA data in the MRSTQED2004 PDF determination. Therefore, the MRSTQED2004 PDFs are defined in the DIS scheme for the factorization of QED effects, i.e. not in the $\overline{\text{MS}}$ scheme as frequently done in
the past (see also Ref. [26]). For the factorization of QCD effects the PDFs are defined in the 
MS scheme as usual.

To extract the collinear divergence from the squared matrix element for the photon-induced
processes we use an extension [20] of the dipole subtraction technique, which has been formulated
to treat the collinear splitting of photons into light fermions \( \gamma \to f \bar{f} \).

### 2.5 Multi-photon final-state radiation

The emission of photons collinear to the outgoing charged lepton leads to corrections that are
enhanced by large logarithms of the form \( \alpha \ln(m_l^2/Q^2) \) with \( Q \) denoting a characteristic scale of
the process. The KLN theorem [24] guarantees that these logarithms cancel if photons collinear
to the lepton are treated fully inclusively. However, since we apply a phase-space cut on the
momentum of the outgoing lepton, contributions enhanced by these logarithms survive if the
momentum of the bare lepton is considered, i.e. if no photon recombination is performed. While
the concept of a bare lepton is not realistic for electrons, it is phenomenologically relevant for
muon final states.

The first-order logarithm \( \alpha \ln(m_l^2/Q^2) \) is, of course, contained in the full \( \mathcal{O}(\alpha) \) correction, so
that \( Q \) is unambiguously fixed in this order. However, it is desirable to control the logarithmically
enhanced corrections beyond \( \mathcal{O}(\alpha) \). This can be done in the so-called structure-function approach
[38], where these logarithms are derived from the universal factorization of the related mass
singularity. The incorporation of the mass-singular logarithms takes the form of a convolution
integral over the LO cross section \( \sigma_0 \),

\[
\sigma_{LLFSR} = \int \sigma_0(p_u, p_d; k_{m}, k_t) \int_0^1 dz \Gamma_{ll}^{LL}(z, Q^2) \Theta_{\text{cut}}(zk_l),
\]

where the step function \( \Theta_{\text{cut}} \) is equal to 1 if the event passes the cut on the rescaled lepton
momentum \( zk_l \) and 0 otherwise. The variable \( z \) is the momentum fraction describing the lepton
energy loss by collinear photon emission. Note that in contrast to the parton-shower approaches
to photon radiation (see e.g. Refs. [11, 15, 16]), the structure-function approach neglects the photon
momenta transverse to the lepton momentum.

For the structure function \( \Gamma_{ll}^{LL}(z, Q^2) \) we take into account terms up to \( \mathcal{O}(\alpha^3) \) improved by
the well-known exponentiation of the soft-photic parts [38],

\[
\Gamma_{ll}^{LL}(z, Q^2) = \frac{\exp \left( -\frac{1}{2} \beta E + \frac{3}{8} \beta h \right)}{\Gamma \left( 1 + \frac{1}{2} \beta h \right)} \frac{\beta h}{2} (1 - z) \frac{3}{2} - 1 - \frac{\beta h}{4} (1 + z) \\
- \frac{\beta h}{32} \left\{ \ln(z) + 4(1 + z) \ln(1 - z) + 5 + z \right\} \\
- \frac{\beta h^3}{384} \left\{ (1 + z) \left[ 6 \ln^2(z) + 12 \ln(1 - z) - 3\pi^2 \right] \\
+ \frac{1}{1 - z} \left[ \frac{3}{2} (1 + 8z + 3z^2) \ln(z) + 6(z + 5)(1 - z) \ln(1 - z) \\
+ 12(1 + z^2) \ln(z) \ln(1 - z) - \frac{1}{2} (1 + 7z^2) \ln^2(z) \\
+ \frac{1}{4} (39 - 24z - 15z^2) \right] \right\},
\]

(2.21)
with \(\gamma_E\) and \(\Gamma(y)\) denoting Euler’s constant and the Gamma function, respectively. The large logarithm is contained in the variable

\[
\beta_l = \frac{2\alpha(0)}{\pi} \left[ \ln \left( \frac{Q^2}{m_l^2} \right) - 1 \right].
\] (2.22)

Here, \(\alpha(0)\) is the fine-structure constant defined in the Thomson limit. The parts solely proportional to a power of \(\beta_l\) correspond to collinear (multi-)photon emission off the lepton, the exponential factor describes resummed soft-photonic effects. The non-logarithmic term “−1” in \(\beta_l\) accounts for a non-singular universal soft-photonic correction.

Technically, we add the cross section (2.20) to the one-loop result and subtract the LO and one-loop contributions

\[
\sigma_{\text{LL}^{1}\text{FSR}} = \int d\sigma_0(p_u, p_d; k_u, k_l) \int_0^1 dz \left[ \delta(1 - z) + \Gamma_{\text{LL}^{1}}(z, Q^2) \right] \Theta_{\text{cut}}(zk_l),
\] (2.23)

contained in (2.20) in order to avoid double counting. The one-loop contribution to the structure function reads

\[
\Gamma_{\text{LL}^{1}}(z, Q^2) = \frac{\beta_l}{4} \left( \frac{1 + z^2}{1 - z} \right). \quad \text{(2.24)}
\]

More precisely, we adapt the value of \(\alpha\) in \(\Gamma_{\text{LL}^{1}}(z, Q^2)\) to the chosen input parameter scheme. Thereby, we introduce an additional higher-order contribution \((\alpha(0) - \alpha) \ln(m_l^2/Q^2)\) so that the \(\alpha \ln(m_l^2/Q^2)\) contribution to the full \(\mathcal{O}(\alpha)\) correction is subtracted exactly. Hence, the procedure of adding higher-order final-state radiation changes also the value of \(\alpha\) in the \(\alpha \ln(m_l^2/Q^2)\) term to \(\alpha(0)\) which is the appropriate coupling for real-photonic effects.

The uncertainty that is connected with the choice of \(Q^2\) enters in \(\mathcal{O}(\alpha^2)\), since all \(\mathcal{O}(\alpha)\) corrections, including constant terms, are taken into account. As default we choose the value

\[Q = \xi \sqrt{s}\] (2.25)

with \(\xi = 1\). In order to quantify the scale uncertainty, we vary \(\xi\) between 1/3 and 3.

### 2.6 Numerical results

#### 2.6.1 Input parameters and setup

The relevant SM input parameters are

\[
\begin{align*}
G_\mu &= 1.16637 \times 10^{-5} \text{GeV}^{-2}, & \alpha(0) &= 1/137.03599911, & \alpha_s(M_Z) &= 0.1189, \\
M_W &= 80.403 \text{GeV}, & \Gamma_W &= 2.141 \text{GeV}, \\
M_Z &= 91.1876 \text{GeV}, & M_H &= 115 \text{GeV}, \\
m_e &= 0.51099892 \text{MeV}, & m_\mu &= 105.658369 \text{MeV}, & m_\tau &= 177.699 \text{GeV}, \\
m_u &= 66 \text{MeV}, & m_c &= 1.2 \text{GeV}, & m_t &= 174.2 \text{GeV}, \\
m_d &= 66 \text{MeV}, & m_s &= 150 \text{MeV}, & m_b &= 4.6 \text{GeV}, \\
|V_{ud}| &= 0.974, & |V_{us}| &= 0.227, \\
|V_{cd}| &= 0.227, & |V_{cs}| &= 0.974,
\end{align*}
\] (2.26)
which essentially follow Ref. [39]. The masses of the light quarks are adjusted to reproduce the hadronic contribution to the photonic vacuum polarization of Ref. [40]. The CKM matrix is included via global factors in the partonic cross sections for the different initial-state quark flavours. Within loops the CKM matrix is set to unity.

As explained in Section 2.2, we adopt the $G_\mu$ scheme (up to the modification of $\alpha$ in the final-state radiation), where the electromagnetic coupling $\alpha$ is set to $\alpha_{G_\mu}$. The charge renormalization constant, which contains logarithms of the fermion masses, drops out in the $G_\mu$ scheme so that our results are practically independent of the light-quark masses. We keep finite light-quark masses in closed fermion loops, their numerical impact is however extremely small. The W-boson resonance is treated with a fixed width without any running effects.

The $\mathcal{O}(\alpha)$-improved MRSTQED2004 set of PDFs [37] is used throughout. The QCD and QED factorization scales are identified and set to the W-boson mass $M_W$.

### 2.6.2 Phase-space cuts and event selection

For the experimental identification of the process $pp/\bar{p}p \rightarrow W^+ \rightarrow l^+\nu_l X$ we impose the set of phase-space cuts

$$p_{T,l} > 25 \text{ GeV,} \quad \hat{p}_T > 25 \text{ GeV,} \quad |\eta_l| < 2.5,$$

where $p_{T,l}$ and $\eta_l$ are the transverse momentum and the rapidity of the charged lepton $l^+$, respectively, and $\hat{p}_T = p_{T,\nu_l}$ is the missing transverse momentum carried away by the neutrino. Note that compared to our previous study [9] we have changed the $\eta_l$-cut to $|\eta_l| < 2.5$, which is a more realistic estimate of the experimental charged-lepton coverage at the LHC. The identification cuts are not collinear safe with respect to the lepton momentum, so that observables in general receive corrections that involve large lepton-mass logarithms of the form $\alpha \ln(m_l/M_W)$. This is due to the fact that photons within a small collinear cone around the charged-lepton momentum are not treated inclusively, i.e. the cuts assume a perfect isolation of photons from the charged lepton. While this is (more or less) achievable for muon final states, it is not realistic for electrons. In order to be closer to the experimental situation for electrons, the following photon recombination procedure is applied:

1. Photons with a rapidity $|\eta_\gamma| > 3$, which are close to the beams, are considered part of the proton remnant and are not recombined with the lepton.\(^1\)

2. If the photon survived the first step, and if the resolution $R_{l\gamma} = \sqrt{(\eta_l - \eta_\gamma)^2 + \phi_{l\gamma}^2}$ is smaller than 0.1 (with $\phi_{l\gamma}$ denoting the angle between lepton and photon in the transverse plane), then the photon is recombined with the charged lepton, i.e. the momenta of the photon and of the lepton $l$ are added and associated with the momentum of $l$, and the photon is discarded.

3. Finally, all events are discarded in which the resulting momentum of the charged lepton does not pass the cuts given in (2.27).

While the electroweak corrections differ for final-state electrons and muons without photon recombination, the corrections become universal in the presence of photon recombination, since the lepton-mass logarithms cancel in this case, in accordance with the KLN theorem. Numerical results are presented for photon recombination and for bare muons.

\(^1\)Note that collinear safety requires that the $|\eta_\gamma|$ cut must be larger than the lepton identification cut on $|\eta_l|$ to avoid events where an almost collinear lepton–photon pair is not recombined because $|\eta_l| \lesssim 2.5$ and $|\eta_\gamma| \gtrsim 2.5$. It turns out, however, that the numerical difference between choosing $|\eta_\gamma| > 3$ and $|\eta_\gamma| > 2.5$ is negligible.
2.6.3 Cross sections and distributions for $pp \to W^+ \to l^+ \nu_l X$ at the LHC

We first consider $W^+$ production at the LHC, i.e. a $pp$ initial state with a centre-of-mass (CM) energy of $\sqrt{s} = 14$ TeV.

In Tables 1 and 2 we present the LO cross section $\sigma_0$ and various types of electroweak corrections $\delta$, defined relative to the LO cross section by $\sigma = \sigma_0 \times (1 + \delta)$. The results are shown for different ranges in the transverse momentum of the charged lepton, $p_{T,l}$, and in the transverse mass of the two final-state leptons, $M_{T,\ell\ell} = \sqrt{2p_{T,l}p_{T,l}(1 - \cos \phi_{\ell\ell})}$, where $\phi_{\ell\ell}$ is the angle between the lepton and the missing momentum in the transverse plane.

For reference, we first update the $O(\alpha)$ NLO corrections for W-boson hadroproduction through the parton process $q\bar{q}' \to W^+ \to l^+ \nu_l$ [9]. The results are given for bare muon final states ($\delta_{qq}^{\mu^{+}\nu_{\mu}}$) and with photon recombination applied ($\delta_{qq}^{\text{rec}}$). As explained above, the mass-singular corrections $\propto \alpha \ln(m_{\mu}/M_{W})$ present in $\delta_{qq}^{\mu^{+}\nu_{\mu}}$ cancel if the photon is recombined, rendering the corresponding correction $\delta_{qq}^{\text{rec}}$ smaller. At large $p_{T,l}$ and $M_{T,\ell\ell}$ the electroweak corrections are dominated by the $O(\alpha)$ Sudakov logarithms discussed in Section 2.3. Note that the relative $O(\alpha)$ corrections $\delta_{qq}$ presented in Tables 1 and 2 are not very sensitive to the choice of the PDF and the choice of the $\eta_l$ cut and thus agree very well with our previous numerical results presented in Ref. [9].

The $O(\alpha)$ corrections originating from the photon-induced processes (Section 2.4) are not included in $\delta_{qq}$, but are shown separately as $\delta_{\gamma q}$ in Tables 1 and 2. They are enhanced at large $p_{T,l}$ because of a new type of contribution where the incoming photon couples to a W boson that is exchanged in the $t$-channel. The photon-induced processes could in principle be used to extract information on the photon content of the proton. However, they are overwhelmed by QCD corrections and QCD uncertainties which strongly affect the $p_{T,l}$ spectrum (see the discussion of NLO QCD corrections below). If, on the other hand, one considers the distribution in the

Table 1: Integrated LO cross sections $\sigma_0$ for $W^+$ production at the LHC for different ranges in $p_{T,l}$ and corresponding relative corrections $\delta$ in the SM.
transverse mass $M_{T,\nu l}$, which is much less sensitive to QCD effects, the impact of $\delta_{qq}$ is below the percent level. The results for $\delta_{qq}$ in Tables 1 and 2 are in good agreement with those presented in Refs. [13, 14]. Note that in Ref. [14] the mass factorization of the collinear $\gamma \to q\bar{q}$ splitting is performed in the $\overline{\text{MS}}$ scheme, while the photon distribution of the MRSTQED2004 PDF set is defined in the DIS scheme as argued above. It turns out, however, that the difference between the calculations in the $\overline{\text{MS}}$ and in the DIS scheme is numerically negligible for hadronic cross sections.

We find that the $\mathcal{O}(\alpha^2)$ high-energy Sudakov logarithms calculated in Section 2.3, labeled $\delta_{\text{Sudakov}}^{(2)}$ in Tables 1 and 2, have a small impact on the cross-section prediction, below 5% even for a transverse lepton momentum $p_{T,l}$ in the TeV range.

The corrections due to multi-photon final-state radiation beyond $\mathcal{O}(\alpha)$ (see Section 2.5) are shown as $\delta_{\text{multi-}\gamma}$ in the tables. Only the genuine higher-order photon effects are included in $\delta_{\text{multi-}\gamma}$, i.e. the one-loop contribution is subtracted. We show $\delta_{\text{multi-}\gamma}$ for the central scale choice $Q = \sqrt{s}$ with an uncertainty estimate obtained from varying the scale $Q$ between $Q = 3\sqrt{s}$ (upper number) and $Q = \sqrt{s}/3$ (lower number). Multi-photon final-state radiation beyond $\mathcal{O}(\alpha)$ has a very small effect on the cross sections displayed in Tables 1 and 2. The largest part of this small contribution is in fact due to the change of the coupling constant $\alpha$ from $\alpha_G = \alpha(0)$ to $\alpha(0)$ in the relative $\mathcal{O}(\alpha)$ correction (see also Section 2.6.5). However, as we shall discuss below, the contribution from multi-photon final-state radiation reaches the percent level near the W resonance and has thus a significant impact on a precision determination of the W mass. A more detailed analysis is needed to quantify the corresponding shift in the determination of $M_W$ (cf. Refs. [1, 15, 41]).

For convenience we combine the above results and display our best estimate for i) the electroweak corrections for muon final states $\delta_{\text{EW}}^{\mu \nu \mu}$, which includes the $\mathcal{O}(\alpha)$ correction to the $q\bar{q}$ initial states, the corrections due to the photon-induced processes, and the multi-photon final-state radiation corrections with the scale choice $Q = \sqrt{s}$, and ii) the total electroweak correction

For comparison, we have also calculated the NLO QCD corrections, evaluated with two different choices for the renormalization and factorization scales, $\mu_R = \mu_F = M_W$ ($\delta_{\text{QCD}}^{\mu=M_W}$) and $\mu_R = \mu_F = M_{T,W}$ with $M_{T,W}^2 = M_W^2 + p_{T,W}^2$ ($\delta_{\text{QCD}}^{\mu=M_{T,W}}$), where $p_{T,W}$ is the transverse momentum of the $W$ boson to be evaluated on an event-by-event basis. We have compared our NLO QCD results for $\delta_{\text{QCD}}^{\mu=M_W}$ with those obtained from MCFM [42] and find good agreement. In the QCD case, there is of course only initial-state radiation and thus no technical need for a recombination procedure of the charged lepton with a possible additional jet. Rather, one should employ a separation cut between lepton and jet to allow for a clean event selection. However, since we only want to give a rough estimate of the size of QCD effects for comparison with the electroweak corrections, for simplicity, we do not include any sort of separation cut. As indicated above, the QCD corrections are extremely large at large $p_{T,l}$ so that the electroweak corrections to the $p_{T,l}$ distribution are overwhelmed by QCD uncertainties. The $M_{T,\nu l}$ distribution, on the other hand, is much less sensitive to higher-order QCD effects. It is invariant under transverse boosts to first order in the velocity of the $W$ boson and thus not strongly affected by a transverse momentum of the $W$ boson induced by gluon radiation at NLO QCD [43].

The size of the QCD corrections to the $p_{T,l}$ distribution can be reduced by applying a jet veto. Table 3 shows the impact of a jet veto on the NLO QCD calculation where we restrict the additional parton to a transverse momentum $p_{T,jet} (= p_{T,W}$ at NLO) $< 50$ GeV. Of course, the jet veto also reduces the size of the photon-induced processes as demonstrated in Table 3.

In Figures 1 and 2 we show the differential cross sections and the corresponding corrections with respect to the transverse momentum $p_{T,l}$ and the transverse mass $M_{T,\nu l}$, respectively. The distributions show the well-known kinks at $p_{T,l} \approx M_W/2$ and $M_{T,\nu l} \approx M_W$, which are used in the $W$-mass determination. Near these kinks the correction $\delta_{qq}$ reaches the order of 10% for bare muons and is reduced to about 5% after photon recombination. Near the resonance region, the corrections from photon-induced processes are very small. Multi-photon emission, on the other hand, reaches the percent level near $p_{T,l} \approx M_W/2$ and $M_{T,\nu l} \approx M_W$ and induces some distortion that affects the $M_W$ determination from the shape of the $M_{T,\nu l}$ distribution. The two-loop Sudakov corrections are, of course, completely negligible near the $W$ resonance and are thus not displayed in Figures 1 and 2.

2.6.4 Cross sections and distributions for $p\bar{p} \rightarrow W^+ \rightarrow l^+\nu_l X$ at the Tevatron

We also present numerical results for $W$ production at the Tevatron, i.e. a $p\bar{p}$ collider with a CM energy of $\sqrt{s} = 1.96$ TeV. We again use the phase-space cuts of (2.27) and the photon recombination procedure specified in the previous section.

Tables 4/5 and Figures 3/4 display the LO cross section $\sigma_0$ and the various relative corrections $\delta$ as a function of the transverse momentum and transverse mass. The electroweak corrections are typically of the same size as those discussed for the LHC, and also show the same qualitative features. It is obvious that the high-energy Sudakov regime is not phenomenologically relevant for $W$ production at the Tevatron, and that the size of the two-loop Sudakov corrections at moderate $p_T^l$ and $M_{T,\nu_l}$ is no reliable estimate of the theoretical uncertainty from missing electroweak two-loop corrections.

2.6.5 Comparison with existing results on multi-photon final-state radiation

Multi-photon radiation has also been included in the Monte Carlo programs \textit{Winhac} \cite{16} and \textit{Horace} \cite{15} within a parton-shower approach in leading logarithmic accuracy. The program \textit{Horace}, in particular, combines multi-photon radiation with the $O(\alpha)$ electroweak corrections. In the following, we will compare our results for multi-photon final-state emission within the structure-function approach defined in Section 2.5 with the \textit{Horace} results as presented in Ref. \cite{16}.

Adopting the setup of Ref. \cite{16}, i.e. the choice of SM input parameters, the identification cuts for bare leptons, and the $\alpha(0)$ input-parameter scheme, we find excellent agreement with the \textit{Horace} result for the leading order and the $O(\alpha)$ corrections, as expected from earlier tuned comparisons \cite{12}.

Figure 5 shows the multi-photon final-state corrections to the distributions in $p_{T,l}$ and $M_{T,\nu_l}$ for the muon final state. Here $\delta^{\alpha(0)}_{\text{multi-}\gamma}$ is the result of our multi-photon correction in the $\alpha(0)$ scheme in the setup of Ref. \cite{16}. The band indicates the dependence on the QED scale (2.25), with the factor $\xi$ varied between 1/3 and 3. The result of \textit{Horace} is denoted $\delta^{\text{Horace}}_{\text{multi-}\gamma}$. For $p_{T,l}$ and $M_{T,\nu_l}$ values below and at the Jacobian peak, the relative corrections differ by less than 0.1%. Above the Jacobian peak the comparison shows larger deviations (about 0.2%) which are comparable to the statistical fluctuations of the \textit{Horace} results. The level of agreement is satisfactory, keeping in mind that the structure-function and parton-shower approaches involve different approximations. In fact, the difference between these approximations should be viewed as a lower bound on the theoretical uncertainty.

Figure 5 also shows the multi-photon correction $\delta_{\text{multi-}\gamma}$, as defined in Section 2.5, which in contrast to $\delta^{\alpha(0)}_{\text{multi-}\gamma}$ contains the formal two-loop effect $(\alpha(0) - \alpha_{G\mu}) \ln(m_l^2/Q^2)$ induced by changing $\alpha_{G\mu}$ to $\alpha(0)$ in the leading photonic $O(\alpha)$ correction in the $G\mu$ scheme. Of course, this contribution does not reflect a genuine new multi-photon effect but only a different partitioning of the total correction into an $O(\alpha)$ and a higher-order QED part.

3 Supersymmetric corrections in the MSSM

Non-standard physics could affect the W-boson cross-section prediction and thus bias the precision determination of Standard Model parameters from W-boson observables at hadron colliders. To quantify the impact of new physics on the W cross section in a concrete model, we have calculated the $O(\alpha)$ electroweak and $O(\alpha_s)$ strong corrections to $pp/p\bar{p} \rightarrow W^+ \rightarrow l^+\nu_l X$ within the MSSM.
\[ p\bar{p} \rightarrow l^+ \nu_l X \text{ at } \sqrt{s} = 1.96 \text{ TeV} \]

3.1 Supersymmetric QCD and electroweak corrections

The SUSY-QCD corrections comprise gluino–squark loops which contribute to the $q\bar{q}'W$ vertex correction and to the quark wave-function renormalization.

To obtain the electroweak SUSY corrections, we calculate the complete electroweak $O(\alpha)$ corrections in the MSSM and subtract the SM corrections, so that the MSSM corrections can be added to the SM predictions of the previous section without double counting. This procedure applies to the vertex, box, and self-energy corrections as well as to the counterterms and $\Delta r$. The diagrams for the genuine SUSY vertex and box corrections are shown in Figures 6 and 7, respectively. The subtraction is only non-trivial for contributions from the Higgs sector where the SM and MSSM vertex appears with different couplings. However, for massless external fermions the Higgs sector only contributes to the $W$-boson self-energy and to renormalization constants. The mass of the lightest MSSM Higgs boson is used as SM input when we subtract the SM contribution to the correction. Hence, for ultimate precision, one would have to calculate the SM corrections with the appropriate Higgs mass.

The diagrammatic calculation is performed in two almost independent ways. Both calculations use FeynArts [21] to generate the relevant (MSSM) diagrams. One of the calculations then employs FormCalc and LoopTools [22] to perform the algebraic calculation and the loop integrals while the other calculation uses a completely independent set of in-house routines for both the algebraic calculation and for the numerical evaluation.

3.2 Numerical results

3.2.1 Input parameters and setup

The SM input parameters and the setup of the calculation (input parameter scheme, PDFs, cuts, etc.) are chosen as described in Section 2.6.1.

To study the dependence of the corrections on the SUSY breaking parameters, we show results for all the SPS benchmark scenarios [44]. The generic suppression of the genuine SUSY corrections turns out to be rather insensitive to a specific scenario. We therefore refrain from further restricting the SPS coverage by taking into account recent experimental bounds in favour
of a broader scope in the SUSY parameter space. The SPS points are defined by the low-energy SUSY breaking parameters which determine the spectrum and the couplings. For the ten benchmark scenarios under consideration in this work, this input [45] is tabulated in Appendix A.

Dependent SUSY parameters, such as Higgs, chargino, neutralino, or sfermion masses, are calculated from the SPS input using tree-level relations. Since the impact of the fermion masses of the first two generations is negligible, these masses are set to zero in the calculation of the corresponding sfermion mass matrices. Following this approach the SUSY corrections do not depend on the fermion generations in the partonic process $u \bar{d} \rightarrow l^+ \nu_l$. In particular, the SUSY corrections presented below are valid for both outgoing electrons and muons.

### 3.2.2 Corrections to partonic cross sections

In order to exhibit the typical features of the SUSY corrections it is instructive to first discuss the inclusive partonic cross section $\hat{\sigma}_0$ evaluated at a fixed partonic CM energy $\sqrt{\hat{s}}$. Here, no cuts are applied. In Figure 8 we display the LO result and the SUSY-EW and SUSY-QCD corrections as a function of the parton energy $\sqrt{\hat{s}}$ for the ten different SPS scenarios.

The SUSY-QCD corrections turn out to be completely negligible for parton energies below 1 TeV, as the SPS scenarios involve heavy squarks and gluinos which effectively decouple. The SUSY-QCD corrections reach the $+1\%$ level only when the sum of the gluino and a squark mass equals $\sqrt{\hat{s}}$, which typically happens between 1 and 2 TeV for the SPS scenarios. For even larger parton energies well above the squark/gluino mass scale the SUSY-QCD corrections turn

---

Figure 6: Classes of diagrams for the additional vertex corrections within the MSSM. The neutralinos $\tilde{\chi}^0$, charginos $\tilde{\chi}$, squarks $\tilde{q} (q = u, d)$ and sleptons $\tilde{l}$ represent the different possible mass eigenstates.

Figure 7: Classes of diagrams for the additional box corrections within the MSSM. The neutralinos $\tilde{\chi}^0$, charginos $\tilde{\chi}$, squarks $\tilde{q} (q = u, d)$ and sleptons $\tilde{l}$ represent the different possible mass eigenstates.
Figure 8: Total partonic LO cross section $\hat{\sigma}_0$ and corresponding relative SUSY-EW and SUSY-QCD corrections $\delta$ as function of the partonic CM energy $\sqrt{\hat{s}}$ for the different SPS scenarios.
negative and become logarithmically enhanced with increasing $\hat{s}$. In Figure 8, the corrections are only shown up to the phenomenologically relevant region $\sqrt{\hat{s}} = 2$ TeV such that the asymptotic behavior is not visible.

The EW corrections turn on at smaller $\sqrt{\hat{s}}$ and exhibit peaks which correspond to sparticle thresholds. Specifically, corrections at the $\pm 1\%$ level occur if the sum of a neutralino and a chargino mass equals $\sqrt{\hat{s}}$ and if the sleptons and squarks in the model are heavy compared to this mass scale. The corrections then rise logarithmically with $\hat{s}$ to positive values. At the mass scale of the sleptons and squarks there is an additional negative contribution to the correction which is less peaked than the gaugino peaks and which washes out the gaugino peaks if the corresponding regions overlap.

3.2.3 Corrections to hadronic cross sections

To calculate the hadronic MSSM cross section we apply the same phase-space cuts as for the SM analysis. However, since the MSSM corrections are purely virtual, the kinematics of the relevant events is as in leading order, i.e. photon recombinatation is irrelevant and $M_{T,\nu l} = 2p_{T,l}$.

In Table 6, we show the integrated cross section for different ranges in $p_{T,l}$ in analogy to the SM analysis in Section 2.6. As expected, the corrections for relatively low $p_{T,l}$ cuts are negligible at the sub-per-mille level. Only in the high-$p_{T,l}$ tail, the EW corrections reach the percent level if the SUSY spectrum is light enough. This rise in the corrections in the high-$p_{T,l}$ tail depends on the mass scale of the relevant SUSY particles in the loops. The maximum of the corrections is reached for the SPS 2 scenario where the gauginos are particularly light and the squarks and sleptons are so heavy that their negative contribution becomes effective only at even larger $p_{T,l}$.

SPS 2 is also the only scenario for which the EW corrections in the $p_{T,l}$ distribution, as shown in Figure 9, almost reach the percent level for $p_{T,l} < 100$ GeV due to the light gauginos. In the W-resonance region the corrections are extremely small and flat in $p_{T,l}$. Only extremely light gauginos with masses smaller than $M_W$ could impact the precise determination of the W mass. Experimental bounds on the mass of the lightest chargino $M_{\tilde{\chi}^\pm} > 100$ GeV [39] rule out such a scenario. Note that the SUSY-QCD corrections are multiplied by a factor of 10 in the plot.

The analogous results for the Tevatron are shown in Table 7 and Figure 10.

4 Conclusions

Single-W-boson production is one of the cleanest hadron collider processes and will be used to precisely determine Standard Model parameters like the W-boson mass and width. In order to match the envisaged high experimental accuracy, it is mandatory to reduce the theoretical uncertainty of the cross-section prediction to a level of one percent or better.

We have studied radiative corrections to single-W-boson production, $pp/p\bar{p} \rightarrow W^+ \rightarrow l^+\nu_l X$, at the LHC and at the Tevatron. We have completed our previous calculation of the $\mathcal{O}(\alpha)$ electroweak corrections [9] by including photon–quark scattering processes. These photon-induced contributions turn out to be considerable at large lepton transverse momentum. However, they do not significantly affect the distribution in the lepton–neutrino transverse mass $M_{T,\nu l}$. We have furthermore discussed the impact of electroweak effects beyond $\mathcal{O}(\alpha)$, specifically the Sudakov logarithms which arise in the high-energy regime. The leading $\mathcal{O}(\alpha^2)$ Sudakov logarithms, which we consider as a measure for the electroweak two-loop effects, turn out to be small, below 5% even for transverse lepton momenta $p_{T,l}$ in the TeV range. Corrections due to multi-photon final-state radiation beyond $\mathcal{O}(\alpha)$ reach the percent level near the W resonance and distort the shape of the $p_{T,l}$ and $M_{T,\nu l}$ distributions. Given the high experimental accuracy envisaged
$pp \rightarrow t^+ \nu t X$ at $\sqrt{s} = 14$ TeV

specifically at the LHC, it is therefore mandatory to control the effects of multi-photon emission in the determination of the W mass.

Finally, to study the impact of new physics on the W cross section in a concrete model, we have calculated the $\mathcal{O}(\alpha)$ electroweak and $\mathcal{O}(\alpha_s)$ strong corrections to $pp/p\bar{p} \rightarrow W^+ \rightarrow l^+\nu_lX$ within the MSSM. The supersymmetric corrections turn out to be negligible in the vicinity of the W resonance for viable MSSM scenarios, reaching the percent level only at very high lepton transverse momenta and for specific choices of the supersymmetric parameters. Effects from virtual SUSY particles would thus not spoil the status of single-W-boson production as one of the cleanest Standard Model candles at hadron colliders.

**Acknowledgments**

We are grateful to Ansgar Denner and Stefano Pozzorini for discussions about electroweak high-energy logarithms. We would like to thank Carlo Carloni Calame, Guido Montagna, Oreste Nicrosini and Alessandro Vicini for providing us with the Horace results. SD and MK thank the Galileo Galilei Institute for Theoretical Physics in Florence for the hospitality and the INFN for partial support during the completion of this work.

**A SPS benchmark scenarios**

For the SPS benchmark [44] scenarios discussed in this work we use the low-energy input specified in Table 8. The input variables are the ratio $t_\beta$ of the vacuum expectation values of the Higgs bosons giving rise to up- and down-type fermion masses, the mass of the CP-odd Higgs boson, $M_{A_0}$, the supersymmetric Higgs mass parameter $\mu$, the electroweak gaugino mass parameters $M_{1,2}$, the gluino mass $m_{\tilde{g}}$, the trilinear couplings $A_{\tau, t, b}$, the scale at which the $\overline{\text{DR}}$-input values are defined, $\mu_{\overline{\text{DR}}}$, the soft SUSY-breaking parameters in the diagonal entries of the squark and slepton mass matrices of the first and second generations $M_{f_i}$ (where $i = L, R$ refers to the left- and right-handed sfermions, $f = q, l$ to quarks and leptons, and $f = u, d, e$ to up and down quarks and electrons, respectively), and the analogous soft SUSY-breaking parameters for the third generation $M_{f_i}^{3G}$.
