Freeze–out and coagulation in pre–protostellar collapse

D.R. Flower¹, G. Pineau des Forêts²,³, and C.M. Walmsley⁴

Abstract. We study the changes in physical and chemical conditions during the early stages of collapse of a pre–protostellar core, starting from initial conditions appropriate to a dense molecular cloud and proceeding to the “completely depleted” limit. We allow for molecular desorption from the grain surfaces and follow the evolution of the ionization degree and the ionic composition as functions of time and density. The timescale for collapse is treated as a parameter and taken equal to either the free–fall or the ambipolar diffusion time. The processes of freeze–out on to the dust grains and of coagulation of the grains were treated simultaneously with the chemical evolution of the medium in the course of its collapse. When proceeding at close to its maximum rate, coagulation has important consequences for the degree of ionization and the ionic composition of the medium, but its effect on the freeze–out of the neutral species is modest. An innovation of our study is to calculate the grain charge distribution; this is done in parallel with the chemistry and the dynamics. The grain charge distribution is significant because H⁺ ions recombine predominantly on the surfaces of negatively charged grains. We have also attempted to reproduce with our models the observational result that nitrogen–containing species, such as NH₃ and N₂H⁺, remain in the gas phase at densities for which CO and other C–containing molecules appear to have frozen on to grain surfaces. We conclude that recent measurements of the adsorption energies of N₂ and CO invalidate the interpretation of these observations in terms of the relative volatilities of N₂ and CO. We consider an alternative explanation, in terms of low sticking coefficients for either molecular or atomic N; but this hypothesis requires experimental confirmation. We find that, irrespective of the nitrogen chemistry, the main gas phase ion is either H⁺ or H₂⁺ (and its deuterated isotopes) at densities above 10⁵ cm⁻³; whether H⁺ or H₂⁺ predominates depends sensitively on the rate of increase in grain size (decrease in grain surface area per unit volume of gas) during core contraction. Our calculations show that H⁺ will predominate if grain coagulation proceeds at close to its maximum rate, and H₂⁺ otherwise.

Key words. molecular cloud – depletion – dust – star formation

1. Introduction

The contraction of an interstellar “core” to form a protostar is a process of great current interest. It is clear that this contraction is accompanied by considerable changes both in the characteristics of the grains associated with the core and the chemical composition of the gas. In particular, most molecules containing heavy elements condense on to grain surfaces (Bacmann et al. 2002, Tafalla et al. 2004). For CO and several other species, this process occurs at densities n_H > 3 × 10^4 cm⁻³. Moreover, there is evidence in several objects for a “molecular hole” at densities above 10⁶ cm⁻³, where material containing C,N,O is in solid form and only molecules and ions composed of H and D remain in the gas phase.

In two earlier articles (Walmsley et al. 2004, Flower et al. 2004), we have considered the characteristics of such “completely depleted” regions and have concluded that the degree of ionization of the gas and the relative abundances of the major ions (H⁺, H₂⁺, D₂H⁺, D₃H⁺) are sensitive to the size of the negatively charged grains, with which H⁺ ions recombine. Recent observations of H₂D⁺ and D₂H⁺ (Caselli et al. 2003, Vastel et al. 2004) are compatible with the existence of a zone lacking heavy elements. However, detection of these ions (H₂D⁺ and D₂H⁺) seems to be rare, suggesting that objects containing such a depleted nucleus are in the ultimate phase of evolution, prior to the formation of a protostar. It seems relevant also that the observations suggest that there is an intermediate density range (10⁵ ≤ n_H ≤ 10⁶ cm⁻³) where molecules containing nitrogen, such as NH₃ and N₂H⁺, remain in the gas phase when carbon– and oxygen–containing species
are already depleted out. This effect of differential depletion was believed to be due to the relatively high volatility of N$_2$ (see Bergin & Langer 1997), which remains in the gas phase when CO, for example, has condensed out. However, recent measurements of the adsorption energies of CO and N$_2$, which are found to differ by less than 10% (Oberg et al. 2004), do not support this interpretation. Accordingly, we attempt to account for the differential depletion by varying other (uncertain) parameters of the model.

An important issue is the extent to which grain coagulation takes place during contraction, thereby influencing the timescales for molecular depletion. Studies of this process (e.g. Ossenkopf 1993, Ossenkopf & Henning 1994, Suttner & Yorke 2001) suggest that, at densities $10^5 \lesssim n_H \lesssim 10^7$ cm$^{-3}$, grains grow in size, although not to the same extent as in protoplanetary disks, where the density is higher. The grain opacity per H nucleus, defined here as $(n_g/n_H)\pi a_g^2$, where $n_g$ is the number density of grains of radius $a_g$, and $n_H/n_H = n$(H) + 2$n$(H$_2$), is expected to decrease but not sufficiently to prevent depletion on to grain surfaces (whose rate is proportional to the same parameter); this is consistent with what is known about the mm–sub-mm opacity of prestellar cores (e.g. Bianchi et al. 2003, Kramer et al. 2003).

With the above points in mind, we have undertaken calculations of the evolution of the chemical composition of such a contracting core. Our work is similar in some respects, but differs in others, to studies of the surface and gas–phase chemistries in a contracting core by Aikawa et al. (2001, 2003, 2005), as well as the time–dependent calculations of Roberts et al. (2003) and the recent study of Bonnor–Ebert spheres by Lee et al. (2004). Our model incorporates a less detailed treatment of the gas–phase chemistry, and we do not attempt to treat surface reactions explicitly. Instead, we have emphasized the evolution of grain charge and size with time and the consequences for the ion chemistry, which we perceive to be a key aspect of the problem. The grain size (through the grain surface area) influences the relative abundances of H$^+$ and H$_3^+$, which are likely to be the major ions during the later phases of core contraction. Our models bring out the important role played under some circumstances by H$^+$, whose significance appears to have been neglected – or, at least, not emphasized – in earlier studies.

In Section 2 of this article, we summarize our formulation of the problem. In Section 3, we consider the critical input parameters of the model. Our main results are given in Section 4 and our concluding remarks in Section 5.

2. Formulation

We consider the evolution of a contracting sphere (“core”) of gas and dust and, for simplicity, we use equations applicable to free–fall, homologous, isothermal collapse. This procedure allows us to parametrize the dynamical behaviour in terms of a collapse timescale, $\tau_c$, which we vary between a minimum value, taken to be the free–fall time, $\tau_{ff}$, and a maximum value, defined by the ambipolar diffusion timescale, $\tau_{ad}$ (see below), both evaluated according to the initial conditions in the medium. In practice, the ambipolar timescale is about an order of magnitude larger than the free–fall time. Thus, $\tau_c$ spans timescales between the magnetically subcritical case, in which the magnetic flux suffices to prevent collapse, and the magnetically supercritical case, where collapse can take place immediately.

The equation which determines the variation of the radius $R$ of the core with time $t$ is

$$\frac{1}{R} \frac{dR}{dt} = \frac{1}{x} \frac{dx}{dt} = -\frac{\pi}{2\tau_c x} \left(1 - \frac{x}{x^*}\right)^\dagger$$

(1)

where $x = R/R_0 \leq 1$ and $R_0$ is the initial radius of the condensation. The timescale for free–fall collapse is (Spitzer 1978)

$$\tau_{ff} = \left[\frac{3\pi}{32G\rho_0}\right]^\dagger$$

(2)

where $\rho_0$ is the initial mass per unit volume. In spherical collapse, the mass density $\rho$ varies with time $t$ according to

$$\frac{1}{\rho} \frac{d\rho}{dt} = -\frac{3}{x} \frac{dx}{dt}$$

(3)

In practice, the collapse is described by equation (1), with the timescale $\tau_c$ taken to be either $\tau_{ff}$ or the ambipolar diffusion timescale, $\tau_{ad}$, to be defined below. As already noted, $\tau_{ad}$ is about an order of magnitude larger than $\tau_{ff}$.

The medium contains neutral gas, positive ions and electrons; it also contains neutral and (mainly negatively) charged grains. The number density, $n$, of the gas–phase neutrals is determined by

$$\frac{1}{n} \frac{dn}{dt} = -\frac{3}{x} \frac{dn}{dt} + \frac{\mathcal{N}}{n}$$

(4)

where $\mathcal{N}$ is the rate per unit volume at which neutrals are created in the gas phase by chemical reactions. Similarly, for the positive ions in the gas phase

$$\frac{1}{n_+} \frac{dn_+}{dt} = -\frac{3}{x} \frac{dn_+}{dt} + \frac{\mathcal{N}_+}{n_+}$$

(5)

Analogous equations are solved for each of the chemical species which intervene in the chemistry.

Central to our approach, and distinguishing it from previous work, is the self–consistent calculation of the change in the grain cross section which occurs owing to coagulation and to freeze–out from the gas phase. The grains are assumed to have a unique radius, determined initially by the grain:gas mass ratio and the mass density of the grain material. Subsequently, the grain radius varies owing to the freeze–out of gas–phase constituents on to the surfaces of the grains and to grain coagulation. The rate of variation of the grain number density is given by

$$\frac{1}{n_g} \frac{dn_g}{dt} = -\frac{3}{x} \frac{dn_g}{dt} + \frac{\mathcal{N}_g}{n_g}$$

(6)
where \( n_g \) is the grain number density. The first term on the right hand side of this equation represents the rate of increase of the number density owing to the compression associated with the (spherical) collapse; the second represents the rate of decrease of the grain number density owing to coagulation. When two grains stick together, only one grain remains, and hence the rate per unit volume at which the grains are removed through coagulation is \( N_c = -\langle \sigma v \rangle n_g^2 \). The method used to determine the rate constant \( \langle \sigma v \rangle \) is presented in Appendix A. We have assumed the grains to be spherical, which minimizes their surface area and effective cross section for a given volume. Clearly, non-spherical grains would have a larger cross section.

In addition to the free-fall timescale [equation (2)], we evaluate the ambipolar diffusion timescale from

\[
\tau_{ad} = \frac{2}{\pi G m_a^2} \sum_i \frac{m_i}{n} \frac{m_i m_a}{m_i + m_n} \langle \sigma v \rangle_{in}
\]

(cf. Flower & Pineau des Forêts 2003a) for both positive ions and charged grains (in which case \( m_i \gg m_n \)) and adopt the larger of the two values. We use the expression of Osterbrock (1961) for the rate coefficient for momentum transfer in a collision between an ion and a neutral particle,

\[
\langle \sigma v \rangle_{in} = 2.41 \pi \langle \sigma^2 a_n / m_{in} \rangle \frac{\mu}{\mu_n}
\]

where \( m_{in} = m_i m_n / (m_i + m_n) \) is the reduced mass and \( \alpha_n \) is the polarizability of the neutral. For collisions between neutrals and charged grains, we take \( \sigma = \pi a_g^2 \) and \( v = (8 k_B T_n / \pi m_n)^{\frac{1}{2}} \), where \( T_n \) is the temperature of the neutral gas.

3. Model

Adopting the initial conditions in steady-state, the condensation was allowed to undergo isothermal collapse, as described in Section 2. The dynamical and chemical rate equations were solved simultaneously. The grain number density was determined by the competing effects of compression, arising from the collapse, and coagulation, which tends to reduce the total number of grains [cf. equation (3) above]. The grain radius was calculated self-consistently as a function of time, \( t \), from the grain number density and the total mass of material currently in the solid phase, allowing for the continuing adsorption of heavy species on to the grains. In practice, adsorption has only a minor effect on \( a_g \), as a mantle of ices is assumed to exist before the onset of collapse; coagulation is a much more significant mechanism for increasing \( a_g \).

3.1. Initial conditions

The initial distribution of the elemental abundances across the gas phase and the solid phase (i.e. grains) is given in Table 1. The elemental abundances derive from the study of Anders & Grevesse (1989), and the depletions from Savage & Sembach (1996), Gibb et al. (2000), and Sofia & Meyer (2001). ‘Depletion’ denotes the fraction of the element in the solid phase (grains). Numbers in parentheses are powers of 10.

| Element | Fractional abundance | Gas phase | Solid phase | Depletion |
|---------|----------------------|-----------|-------------|-----------|
| H       | 1.00                 | 1.00      | 3.95(-4)    | 0.0       |
| He      | 1.00(-1)             | 1.00(-1)  | 0.0         | 0.0       |
| C       | 3.55(-4)             | 8.27(-5)  | 2.72(-4)    | 0.77      |
| N       | 7.94(-5)             | 6.39(-5)  | 1.55(-5)    | 0.20      |
| O       | 4.42(-4)             | 1.24(-4)  | 3.18(-4)    | 0.72      |
| Mg      | 3.70(-5)             | 3.70(-5)  | 1.0         | 1.0       |
| Si      | 3.37(-5)             | 3.37(-5)  | 1.0         | 1.0       |
| S       | 1.86(-5)             | 0.60(-6)  | 1.80(-5)    | 0.97      |
| Fe      | 3.23(-5)             | 1.50(-9)  | 3.23(-5)    | 1.0       |

The computer code was run to determine the steady-state abundances of the chemical species in the gas phase (neglecting any further depletion) by the simple expedient of specifying a timescale for collapse, \( \tau_c \), in equation (1) which is much greater than the chemical equilibrium timescale; 92 gas–phase species and almost 800 chemical reactions were included in the model. The gas–phase chemistry included ion–neutral, neutral–neutral, and dissociative recombination reactions involving species containing H, He, C, N, O and S. The branching ratio for the dissociative recombination of \( \text{N}_2 \text{H}^+ \), to N or \( \text{N}_2 \), was taken from the recent measurements of Geppert et al. (2004). Ionization by cosmic rays, both direct and indirect (by the electrons released), was taken into account. Adsorption of neutral species on to grains, and desorption of the hydrogenated products of the grain–surface chemistry following cosmic ray heating of the grains, were also incorporated (see below). The rate of cosmic ray ionization of hydrogen was taken to be \( \zeta = 1 \times 10^{-17} \) s\(^{-1}\). The list of species and the complete set of chemical reactions included in the model are available from http://massey.dur.ac.uk/drf/protostellar/species_chemistry.

The initial value of the grain radius was taken to be \( a_g = 0.05 \mu m \), which yields a grain opacity, defined here as \( n_g \pi a_g^2 \), of \( 1.6 \times 10^{-21} n_{H} \) cm\(^{-1}\), assuming the density of the grain material to be 2 g cm\(^{-3}\). Adopting the grain–size distribution of Mathis et al. (1977), with limits of \( 0.01 \leq a_g \leq 0.3 \mu m \) to the distribution, and assuming the canonical value of 0.01 for the dust:gas mass ratio, one
obtains the same value of $n_g \pi a_g^2$. [We note that the value of $a_g$ required to reproduce a given value of $n_g \pi a_g^2$ depends only on the adopted size distribution and its limits, and not on the density of the grain material nor the dust/gas mass ratio; see Appendix B.]

### 3.2. Grain charge distribution

In view of the significance of grains for the state of charge of the medium, the grain charge distribution was computed in parallel with the chemical composition, allowing for electron attachment and detachment and electron–ion recombination on grain surfaces (cf. Flower & Pineau des Forêts 2003b, Section 2.2). Singly charged and neutral grains were considered. In the case of collisions between charged particles and oppositely charged grains, the ‘focusing’ effect of the Coulomb attraction was included by means of equation (3.4) of Draine & Sutin (1987). In the case of collisions between charged particles and neutral grains, the attraction arising from the polarization of the grain by the incoming particle was included by means of their equation (3.3). For example, the rate per unit volume of electron attachment to neutral grains was evaluated as $n_e n_g \pi a_g^2 [1 + (\pi e^2/2a_g k_B T_e)]^{0.5} |8 k_B T_e/(\pi m_e)|^{0.5} s_e$, where $n_e$ is the electron density, $n_g$ is the density of the neutral grains, $T_e$ is the electron temperature (taken equal to the gas temperature, $T = 10$ K), $m_e$ is the electron mass, and $s_e = 0.5$ is the electron sticking coefficient. The initial value of the total grain number density, $n_g$, was calculated self-consistently from the elemental depletions, the specified grain radius, and the mean density of the grain material, taken to be 2 g cm$^{-3}$ at all times. The grain charge distribution is not sensitive to the assumed grain size, as the dominant charge-changing processes – electron attachment to neutral grains and ion recombination with negatively charged grains – scale approximately with $a_g^3$ and with $a_g$, respectively, under the conditions which are relevant here.

### 3.3. Adsorption and desorption

The rate coefficient for adsorption of neutral species on to the grains was taken to be $\pi a_g^2 [8 k_B T/\pi m_o]^{0.5} S_n$, where $m_o$ is the mass of the neutral. The ‘sticking’ coefficient $S_n = 1$, unless stated otherwise; we assumed that He remained in the gas phase and that H$_2$ was returned to the gas phase after forming on the grains. The geometrical cross section of the grain is adopted in this expression for the rate coefficient. Although the potential arising from the polarization of the grain by a charged particle can be significant (see Section 3.2), the potential due to the polarization of a neutral by a charged grain is negligible; this is because the polarizability of a grain is orders of magnitude larger than the polarizabilities of the neutral gas–phase species, owing to the much larger size of the grain.

The recombination of positive ions with electrons on the surfaces of negatively charged grains releases the electron binding energy, which is typically a few eV and large compared with the adsorption energies of the neutral species. Accordingly, we have assumed that the neutrals which are formed in this way are returned immediately to the gas phase. The attachment of ions to neutral grains is a relatively minor process, owing to the predominance of negatively charged grains (see Section 4.3 below) and to Coulomb focusing in collisions of ions with negatively charged grains. Consequently, we have neglected the adsorption of ions on to grains when computing the rate of freeze–out of gas–phase species.

With the exception of H$_2$, which desorbs following its formation, desorption of molecules was assumed to be controlled by the heating of grains which occurs owing to cosmic ray impact (Léger et al. 1985). The rate of desorption of species $i$ per unit volume per unit time from the grains is

$$\sum n_i \pi a_g^2 \gamma \exp \left[ -\left( \frac{E_{nds} - E_{i}^{ads}}{k_B T_{max}} \right) \right]$$

where $n_i^g / \sum n_i^g$ is the fractional abundance of species $i$ on grains, $E_{i}^{ads}$ is the adsorption energy of the species (Aikawa et al. 1996, 1997, 2001), which relate to measurements on pure ices; $T_{max} = 70$ K is the maximum temperature reached by the grains following cosmic ray impact (Hasegawa & Herbst 1993). We adopted $\gamma = 70$ cm$^{-2}$ s$^{-1}$, which yields a rate of desorption for CO which is consistent with the value for ‘spot’ heating, as derived by Léger et al. (1985); the heating arises from the impact of heavy cosmic rays, particularly Fe nuclei. In the case of small grains, ‘whole-grain’ heating may be more important than ‘spot’ heating, and the corresponding value of $\gamma$ would be larger than adopted here.

### 3.4. Coagulation

Grain coagulation was treated as described in Appendix A. The important parameters are the local turbulent speed of the gas, which is assumed to determine the relative speed of the grains, and the critical speed $v_{crit}(a_g)$ below which grains are assumed to coagulate on every collision. Following Tafalla et al. (2004), who observed L1498 and L1517B (see also Barranco & Goodman 1998), we adopted the turbulent line–width as an upper limit to the FWHM of the Gaussian velocity distribution, i.e. $\Delta v \leq 0.12$ km s$^{-1}$, which is approximately $c_s/2$ at $T = 10$ K, where $c_s$ is the adiabatic sound speed. This value may include contributions from motions on scales larger than the mean–free path for grain–grain collisions and hence places an upper limit on $\Delta v$. Accordingly, we have taken $\Delta v = c_s/4$ as our reference value, but we have also run models with $\Delta v = c_s/2$ and $\Delta v = c_s/10$.

The critical speed for coagulation, $v_{crit}$, was taken from Chokshi et al. (1993), unless otherwise stated. We adopted their results for the case of ‘ice’; this seems the most ap-
propriate of the three cases ('ice', 'graphite', 'quartz') considered by Chokshi et al., as the grains already have ice mantles at the start of the calculation. Accordingly,

\[ v_{\text{crit}}(a_g) = 0.1 \ a_g^{-5/6} \]  

(9)

when \( v_{\text{crit}} \) is in cm s\(^{-1} \) and \( a_g \) is in cm. We have assumed that the grains remain spherical throughout. This assumption minimizes the grain radius, and hence the grain opacity per H nucleus, \( (n_g/n_H)\pi a_g^2 \), as the collapse proceeds. We assume also that the density of the grain material is unchanged by coagulation. The critical speed given by equation (9) is greater than the estimate of Suttner & Yorke (2001) but approximately 4 times less than the measurement of Poppe & Blum (1997). We have run some comparison calculations in which \( v_{\text{crit}} \) was taken to be 4 times greater than is given by equation (9).

4. Results

We consider the case of a condensation of gas and dust with an initial number density \( n_H = n(\text{H}) + 2n(\text{H}_2) = 10^4 \) cm\(^{-3} \) and kinetic temperature \( T = 10 \) K. We recall that the rate of cosmic ray ionization of hydrogen was taken to be \( \zeta = 1 \times 10^{-17} \) s\(^{-1} \).

4.1. Freeze–out

Fig. 1 illustrates the freeze–out of selected neutral species, including CO and N\(_2\), on to the grains and the evolution of the fractional abundances of the major ions, including H\(^+\), H\(_3^+\) and HCO\(^+\). Results are shown for a reference model in which coagulation was neglected and the timescale for collapse is determined by the free–fall time, \( \tau_c = \tau_f \). The corresponding density profile, \( n_H(t) \), is also shown in Fig. 1. As will be seen below, collapse gets under way after a few times 10\(^5\) yr, and the neutral species then freeze out rapidly on to the grains. Initially, HCO\(^+\) is the most abundant molecular ion, but it is overtaken by H\(_3^+\) and H\(^+\) as freeze–out proceeds. Ultimately, the degree of ionization of the gas is determined by H\(_3^+\) under the conditions of this model.

The adsorption energy of N\(_2\) which was used to obtain the results in Fig. 1 was 790 K, which is to be compared with \( E_{\text{ads}}^{\text{CO}} = 855 \) K (Oberg et al. 2004). A much larger difference between the adsorption energies of N\(_2\) and CO is required for there to be a significant difference between the density–dependence of the fractional abundances of N\(_2\) and CO, and hence of N\(_2\)H\(^+\) and HCO\(^+\). Another possible explanation of this differential effect will be considered below, in the context of a discussion of the nitrogen chemistry.

The effect of allowing the ambipolar diffusion timescale to regulate the collapse is shown in Fig. 2. As we shall see below, the timescale for ambipolar diffusion is about an order of magnitude larger than the free–fall time, and so freeze–out occurs at lower values of the gas density, before the collapse is under way. Indeed, in this case, freeze–out occurs at densities which are lower than the values of \( n_H \gtrsim 3 \times 10^4 \) cm\(^{-3} \) which have been deduced from observations of CO (cf. Bacmann et al. 2002, Tafalla et al. 2004). Thus, the observational data pertaining to CO depletion favour a collapse timescale of order of the free–fall time. The ‘knee’ which is apparent in the curves arises at the fractional abundance at which cosmic ray desorption begins to be significant; this occurs marginally sooner for N\(_2\) than for CO, owing to the smaller (by 65 K) adsorption energy of the former species.

Including coagulation, with the expression of Chokshi et al. (1993) for \( v_{\text{crit}}(a_g) \) [equation (9)], has very little effect on the results, as may be seen by comparing Figs. 2a and 2b: the ‘free–fall’ results in Fig. 2a (the upper pair of curves) are almost coincident with the full curves in Figs. 2a. Even when the (4 times larger) values of \( v_{\text{crit}}(a_g) \) are adopted, following Poppe & Blum (1997), which possibly yields an upper limit to the rate of coagulation, its effect on the evolution of the fractional abundances of the neutral species is not large, as may be seen from Fig. 2b.

4.2. Timescales

In Fig. 3 we plot the grain radius, \( a_g \), as a function of the gas density, \( n_H \). Results are shown for the limiting case of no coagulation (\( v_{\text{crit}} = 0 \)) and for \( v_{\text{crit}}(a_g) = 0.1 \ a_g^{-5/6} \) [equation (9); Chokshi et al. (1993)] and \( v_{\text{crit}}(a_g) = 0.4 \ a_g^{-5/6} \) (Poppe & Blum 1997): \( \Delta v = c_s/4 \), where \( c_s = 0.243 \) km s\(^{-1} \) is the adiabatic sound speed. When equation (9) is adopted, the initial value of the critical speed for coagulation is \( v_{\text{crit}} = 0.0262 \) km s\(^{-1} \), almost an order of magnitude smaller than \( c_s \).

Fig. 3 shows that, when no coagulation occurs, the grain radius, \( a_g \), is practically constant, as the contribution of continuing freeze–out to the size of the grain mantles is small; we have assumed that the grains have a mantle of ices before collapse begins. The rate of coagulation, and hence the rate of increase of the grain radius, \( a_g \), is seen to be sensitive to the critical speed, \( v_{\text{crit}}(a_g) \): increasing the constant of proportionality in equation (9) from 0.1 to 0.4, which is in line with the measurements of Poppe & Blum (1997), has the effect of enhancing significantly the degree of coagulation over the free–fall time. Reducing the turbulent width, \( \Delta \), which is the FWHM of the Gaussian distribution [equation (A.3)], has a similar effect to increasing \( v_{\text{crit}}(a_g) \): increasing the constant of proportionality in equation (9) from 0.1 to 0.4, which is in line with the measurements of Poppe & Blum (1997), has the effect of enhancing significantly the degree of coagulation over the free–fall time. Reducing the turbulent width, \( \Delta \), which is the FWHM of the Gaussian distribution [equation (A.3)], has a similar effect to increasing \( v_{\text{crit}}(a_g) \): increasing the constant of proportionality in equation (9) from 0.1 to 0.4, which is in line with the measurements of Poppe & Blum (1997), has the effect of enhancing significantly the degree of coagulation over the free–fall time. Reducing the turbulent width, \( \Delta \), which is the FWHM of the Gaussian distribution [equation (A.3)], has a similar effect to increasing \( v_{\text{crit}}(a_g) \): increasing the constant of proportionality in equation (9) from 0.1 to 0.4, which is in line with the measurements of Poppe & Blum (1997), has the effect of enhancing significantly the degree of coagulation over the free–fall time. Reducing the turbulent width, \( \Delta \), which is the FWHM of the Gaussian distribution [equation (A.3)], has a similar effect to increasing \( v_{\text{crit}}(a_g) \): increasing the constant of proportionality in equation (9) from 0.1 to 0.4, which is in line with the measurements of Poppe & Blum (1997), has the effect of enhancing significantly the degree of coagulation over the free–fall time. Reducing the turbulent width, \( \Delta \), which is the FWHM of the Gaussian distribution [equation (A.3)], has a similar effect to increasing \( v_{\text{crit}}(a_g) \): increasing the constant of proportionality in equation (9) from 0.1 to 0.4, which is in line with the measurements of Poppe & Blum (1997), has the effect of enhancing significantly the degree of coagulation over the free–fall time. Reducing the turbulent width, \( \Delta \), which is the FWHM of the Gaussian distribution [equation (A.3)], has a similar effect to increasing \( v_{\text{crit}}(a_g) \): increasing the constant of proportionality in equation (9) from 0.1 to 0.4, which is in line with the measurements of Poppe & Blum (1997), has the effect of enhancing significantly the degree of coagulation over the free–fall time.
The gravitational free-fall time, \( \tau_{ff} = 0.43 \times 10^6 \) yr for our initial density \( n_H = 10^4 \) cm\(^{-3}\), is much smaller than the initial ambipolar diffusion timescales for both positive ions and charged grains, \( \tau_{ad}^{\text{ion}} = 3.4 \times 10^6 \) yr and \( \tau_{ad}^{\text{grain}} = 3.6 \times 10^6 \) yr. The timescale for freeze-out of the neutral species on to the grains – the inverse of the adsorption rate – is given by

\[
\tau_{fo} = \left[ n_g \pi a_g^2 v_{th} S \right]^{-1}
\]

where

\[
v_{th} = \left( \frac{8k_B T_n}{\pi m_n} \right)^{1/2}
\]

is the thermal speed, \( T_n \) is the kinetic temperature and \( m_n \) is the mass of the species; \( S \) is the sticking coefficient. Taking \( T_n = 10 \) K and \( m_n = 28 m_H \) (corresponding to CO, as an example) and \( S = 1 \), we obtain \( \tau_{fo} = 2.2 \times 10^5 \) yr initially, when \( a_g = 0.05 \) \( \mu \)m and \( n_H = 10^4 \) cm\(^{-3}\). Thus, the timescale characterizing freeze-out is comparable with the free-fall timescale and much smaller than that for ambipolar diffusion. The timescale for coagulation is

\[
\tau_{cg} = \left[ n_g 4 \pi a_g^2 v_{rel} \right]^{-1}
\]

where \( v_{rel} \) is the relative collision speed. The maximum possible value of \( v_{rel} \) is \( v_{\text{crit}} \) [cf. equation (9)]; adopting \( v_{rel} = v_{\text{crit}} \), we see that

\[
\frac{\tau_{fo}}{\tau_{cg}} \propto \frac{v_{\text{crit}}}{v_{th} S}
\]

With the values of the parameters specified above, we obtain \( \tau_{cg} = 1.8 \times 10^5 \) yr initially, which is approximately equal to \( \tau_{fo} \). However, \( \tau_{cg} \) tends to increase with time, owing to the increase in \( a_g \) and consequent decrease in \( v_{\text{crit}} \). As we have assumed the maximum possible value of \( v_{rel} \) when evaluating \( \tau_{cg} \), we conclude that freeze-out tends to occur more rapidly than coagulation, providing the sticking coefficient \( S \approx 1 \).

### 4.3. Fractional ionization

The significance of ambipolar diffusion and, in particular, the role of elastic scattering between neutrals and charged grains in protostellar collapse have been recognized for some considerable time (Nakano & Umebayashi 1980; Shu et al. 1987; Ciolek & Basu 2000). Whether the timescale for collapse, \( \tau_c \), is determined by ambipolar diffusion or by gravitational free-fall depends on the fractional ionization of the gas [cf. equation (7)] and the degree of charge of the grains.

At early times, \( S^+ \) is the most abundant atomic ion, and its abundance is maintained by charge transfer of \( H^+ \) to \( S \); the source of \( H^+ \) is cosmic ray ionization of hydrogen. When freeze-out of the neutrals on to the grains occurs, the fractional abundance of \( H^+ \) tends to rise as losses through charge transfer reactions (with \( S \) and other neutral species with ionization potentials less than that of \( H \)) decrease. This phenomenon is illustrated in Fig. 4, where the fractional abundances of \( H^+ \) and a selection of other ions are plotted as functions of the gas density, \( n_H \).

The significance of coagulation may be seen by comparing Fig. 4a, in which coagulation is neglected, with Figs. 4b and c, in which coagulation is included.

The recombination of \( H^+ \) with free electrons is a radiative process and hence slow. Consequently, \( H^+ \) ions recombine with electrons predominantly on the surfaces of negatively charged grains. On the other hand, the recombination of \( H^+_3 \) with free electrons is a non-radiative (dissociative) process and intrinsically fast. Using the parameters adopted in our model, the ratio \( R \) of the rate (s\(^{-1}\)) of dissociative recombination of \( H^+_3 \) in the gas phase and its rate of recombination on the surfaces of the (predominantly) negatively charged grains is

\[
R \approx 2 \times 10^{11} x_e a_g^2
\]

where \( x_e = n_e/n_H \) and \( a_g \) is expressed in \( \mu \)m. Thus, when \( a_g = 0.05 \) \( \mu \)m, \( R = 1 \) is attained when \( x_e \approx 2 \times 10^{-9} \); then, \( H^+_3 \) recombines at equal rates on the surfaces of negatively charged dust grains and in the gas phase. Referring to Fig. 4h, we see that this point is reached when \( n_H \approx 10^6 \) cm\(^{-3}\). At lower densities, dissociative recombination predominates, whereas, at higher densities, recombination on the surfaces of negative grains predominates, and the fractional abundances of \( H^+_3 \) and \( H^+ \) vary similarly with \( n_H \).

The ratio of the fractional abundances of \( H^+_3 \) and \( H^+ \)

\[
n(H^+_3)/n(H^+) \approx 18/(1 + R)
\]

for the parameters adopted in our model; this expression agrees well with the numerical results presented in Fig. 4h, in the high density limit, where \( R \to 0 \). (We recall that, owing to the absence of deuterated isotopes in the present model, the number density of \( \text{“}H^*_3 \text{”} \) should be understood as \( n(H^+_3) + n(H^+_3 D^+) + n(H^+_3 D^+ D^+) + n(D^+_3) \)).

In the case where there is no coagulation, as in Fig. 4a, the grain opacity per H nucleus, \( n_g/n_H \pi a_g^2 \), remains practically constant as the collapse proceeds; cf. Fig. 4b. The \( H^+ \) ions are removed (by recombination with electrons on the surfaces of negatively charged grains) on a timescale which is inversely proportional to \( n_g \pi a_g^2 \) and hence to \( n_H \). For \( n_H \leq 10^6 \) cm\(^{-3}\), \( H^+_3 \) ions are removed predominantly by dissociative recombination with free electrons, on a timescale which is inversely proportional to approximately \( n_H^{0.5} \). As a consequence, the fractional abundance of \( H^+_3 \) ions initially increases relative to \( H^+ \) as \( n_H \) increases, and the case of ‘no coagulation’ is characterized by \( n(H^+_3) > n(H^+) \) at high gas densities. On the other hand, when coagulation occurs (assuming \( \Delta v = c_s/4 \) in Fig. 4h, \( n_g/n_H \pi a_g^2 \) decreases as \( n_H \) increases (cf. Fig. 4b)), and the rate of recombination of the \( H^+ \) ions on grains is reduced. Owing to the higher fractional abundance of the free electrons, \( n(H^+_3) < n(H^+) \) at high gas densities when \( v_{\text{crit}}(a_g) = 0.4 a_g^{-3/2} \). These results are summarized in Figs. 4h-c.
The results in Fig. 4 show that the ratio \( n(H^+) / n(H) \) falls substantially when coagulation is introduced: grain growth favours \( H^+ \). On the other hand, the fact that \( H_2^+ \) and \( D_2^+ \) have been observed in pre–protostellar objects (Caselli et al. 2003, Vastel et al. 2004) suggests that the deuterated forms of \( H_2^+ \) may be the dominant gas–phase ions. If so, the present calculations imply that coagulation is not significant in reducing the grain opacity per \( H \) nucleus during the early phases of collapse.

The final panel (d) in Fig. 4 shows the effect of reducing the value of the sticking coefficient for molecular nitrogen to \( S(N_2) = 0.1 \) and should be compared with those in panel (c), where \( S(N_2) = 1 \), the default value for all species which freeze out; the results in Fig. 4 are considered below.

A novelty of the present study is the calculation of the grain charge distribution, in parallel with the chemistry and the dynamics; the charge distribution is significant because \( H^+ \) ions recombine predominantly on the surfaces of negatively charged grains, at a rate which is determined by their opacity per \( H \) nucleus, \( (n_g^−/n_H)\pi a_g^2 \). The higher fractional abundance of free electrons at high gas densities, owing to coagulation (cf. Fig. 4), leads to an increase in the fraction of the grains which are negatively charged; see Fig. 5. The fraction of positively charged grains always remains small. When there is no coagulation, the fraction of neutral grains remains above 10% as the collapse proceeds, whereas, for the maximum rate of coagulation considered in Fig. 5, approximately 95% of the grains are negatively charged by the time \( n_H = 10^7 \, \text{cm}^{-3} \). Nonetheless, the opacity per \( H \) nucleus of the negatively charged grains, \( (n_g^+/n_H)\pi a_g^2 \), decreases as \( v_{\text{crit}} \) increases, owing to the reduction in the total grain opacity per \( H \) nucleus as coagulation proceeds; see Fig. 6.

4.4. Nitrogen chemistry

One problem which all models of the chemistry of prestellar cores have to solve is the variation of the fractional abundances of nitrogen–containing compounds with density. Observations indicate that, whilst most molecules deplete on to grain surfaces at densities of a few times \( 10^4 \, \text{cm}^{-3} \), species containing nitrogen, such as \( \text{NH}_3 \) and \( \text{N}_2 \text{H}^+ \), survive to densities which are an order of magnitude larger (e.g. Tafalla et al. 2004, Belloche & André 2004, Bergin et al. 2002). Chemical modellers have attempted to explain this behaviour by assuming lower values of the adsorption energy for \( \text{N}_2 \) than for \( \text{CO} \) and other abundant neutral molecules; this results in cosmic ray–induced or direct thermal desorption of \( \text{N}_2 \) being more efficient than for \( \text{CO} \). Aikawa et al. (1997, 2001) and Bergin et al. (2002) give \( E_{\text{ads}}^{\text{CO}} = 750 \, \text{K} \) as the adsorption energy of \( \text{N}_2 \) and \( E_{\text{ads}}^{\text{CO}} = 960 \, \text{K} \) as the adsorption energy of \( \text{CO} \), on \( \text{CO} \) ice. On the other hand, recent measurements (Oberg et al. 2004) indicate that the adsorption energies of \( \text{N}_2 \) to \( \text{CO} \) and \( \text{CO} \) to \( \text{CO} \) ice are \( E_{\text{N}_2}^{\text{ads}} = 790 \, \text{K} \) and \( E_{\text{CO}}^{\text{ads}} = 855 \, \text{K} \); we have adopted these values in our calculations but considered the implications of using larger values of \( (E_{\text{CO}}^{\text{ads}} - E_{\text{N}_2}^{\text{ads}}) \). We have concluded that the approximately 10% difference between the binding energies of \( \text{CO} \) and \( \text{N}_2 \), as measured by Oberg et al. (2004), is insufficient to account for the observed differences in fractional abundances, to which reference was made above. We note that, in the present context, it is the ratio between the rates of desorption of \( \text{CO} \) and \( \text{N}_2 \) which is significant and determined by the difference in their adsorption energies; the absolute rates are less crucial.

An possible explanation of the observations is that there is a difference between the sticking coefficients of \( \text{CO} \) and one of the principal forms of gas–phase nitrogen (\( \text{N} \) or \( \text{N}_2 \)). Accordingly, we have carried out calculations in which the sticking coefficient, \( S \), of either \( \text{N} \) or \( \text{N}_2 \) was set equal to 0.1, whilst retaining \( S = 1 \) for all other species; the results of the calculations in which \( S(N_2) = 0.1 \) are shown in Fig. 4. In Fig. 4 and Fig. 5, we compare the free–fall models, including coagulation and with \( S(N_2) = 1 \) or \( S(N_2) = 0.1 \), respectively. In the case of \( S(N_2) = 0.1 \), the fractional abundance of \( \text{N}_2 \text{H}^+ \), which traces \( \text{N}_2 \), decreases rapidly at densities \( n_H \gtrsim 10^8 \, \text{cm}^{-3} \), which is roughly an order of magnitude higher than for the corresponding fall–off of \( \text{HCO}^+ \). The fractional abundance of \( \text{N}_2 \text{H}^+ \) attains values of several times \( 10^{-10} \), \( \text{which are, in fact, larger than the observed values. However, the effect upon the evolution of the major ions, } \text{H}^+ \text{ and } \text{H}_2^+, \text{ is not large, and } \text{N}_2 \text{H}^+ \text{ never becomes a major ion. We conclude that a small sticking coefficient for } \text{N}_2 \text{ could explain the observations; but this assumption is clearly ad hoc and needs experimental verification.} \) \( \text{The other possibility is that the sticking coefficient of atomic nitrogen is small, } S(N) = 0.1. \text{This assumption has the consequence that a substantial fraction of the nitrogen remains in the gas phase, but it does not result in a significant enhancement of the abundance of } \text{N}_2 \text{H}^+, \text{relative to the case in which all the sticking coefficients } S = 1. \text{The reason for this result is to be found in the gas–phase chemistry of nitrogen. The paths to } \text{N}_2 \text{H}^+ \text{ and } \text{NH}_3 \text{ start with the neutral–neutral reactions } \text{N(OH, H)NO and NO(, O)N}_2 \text{ (Pineau des Forêts et al. 1990), whose rates depend on the fractions of } \text{N} \text{ and } \text{OH} \text{ in the gas phase. However, these reactions are so slow that an increase in the initial gas–phase abundance of } \text{N} \text{ has little effect on the abundances of } \text{N}_2 \text{H}^+ \text{ or } \text{NH}_3 \text{ on the timescale of the collapse. Only when the abundance of } \text{N}_2 \text{ is increased directly, by reducing its sticking coefficient or its adsorption energy, are the abundances of } \text{N}_2 \text{H}^+ \text{ and } \text{NH}_3 \text{ enhanced significantly.} \) \( \text{4.5. Validation of previous results} \) \( \text{In our previous calculations of complete depletion in pre–protostellar cores (Walmsley et al. 2004; Flower et al. 2004), we computed abundances in steady–state, neglecting dynamical effects but including deuteration reactions. Although we do not currently consider deuteration reac-} \)
tions in the phase of ‘free–fall’, it is possible to compare
the fractional ionization of the gas and the abundances of the
major ions, H$^+$ and H$_3^+$, over the range of den-
sities considered previously ($2 \times 10^5 \leq n_H \leq 2 \times 10^7$
$\text{cm}^{-3}$). In order to make the appropriate comparison
with our previous work, we plot, in Fig. 4, $n(\text{H}_3^+)/n_H$
from the present calculations, neglecting coagulation, and
$[n(\text{H}_3^+) + n(\text{H}_2\text{D}^+) + n(\text{HD}_2^+) + n(D_3^+)]/n_H$
from our previous study (Walmsley et al. 2004).

As may be seen from Fig. 4, the agreement between the
two calculations is good. Although the abundances of
atomic ions such as Fe$^+$ and, especially, S$^+$ are initially
significant (i.e when $n_H \approx 10^4 \text{cm}^{-3}$), recombination
with electrons, on the surfaces of grains, neutralizes the atomic
ions. By the time that a density of $n_H \approx 10^5 \text{cm}^{-3}$ has
been reached, the principal ions are H$_3^+$ and H$^+$, as pre-
dicted by our earlier calculations, in steady–state. Thus,
even when the collapse is as fast as in the case of ‘free–fall’,
the assumption of a steady–state is a good approximation.

5. Concluding remarks

We have considered the early stages of isothermal col-
lapse of a pre–protostellar core. The initial conditions were
taken to be those appropriate to dense molecular clouds,
with significant fractions of the heavy elements being de-
peted into the cores or the ice mantles of dust grains. The
time for collapse is taken equal to the timescale which
characterizes either free–fall or ambipolar diffusion; the
latter is almost an order of magnitude larger than the for-
er.

The processes of further freeze–out on to the interstel-
lar grains and of coagulation of the grains were included
when calculating the chemical evolution of the medium
in the course of its collapse. Species containing heavy ele-
ments freeze on to the grains in the early phases of the col-
lapse. When ambipolar diffusion determines the timescale
for collapse, freeze–out occurs at densities which are lower
than the values which have been deduced from observa-
tions of CO (cf. Bacmann et al. 2002, Tafalla et al. 2004);
we conclude that the observational data favour a collapse
timescale of order of the free–fall time, rather than the
(larger) ambipolar diffusion time. In this case, coagula-
tions of both NH$_3$ and N$_2$H$^+$ enhanced, relative to CO,
during the course of the collapse. However, we recognize
that the assumption of $S(N_2) \approx 0.1$ is ad hoc and needs experimental verification.

### Appendix A: The rate coefficient for grain
coagulation

We assume that the velocity distribution of the popula-
tion of grains is Gaussian and consider a collision between
two grains, 1 and 2. The $x$-component of the velocity dis-
tribution of grain 1 is given by

$$
\phi(v_{x1}) = \frac{h_1}{\pi \frac{\sigma_x}{2}^2} e^{-h_1^2 v_{x1}^2}
$$

such that

$$
\int_{-\infty}^{\infty} \phi(v_{x1}) \, dv_{x1} = 1
$$

Thus the probability that grain 1 has cartesian velocity
components in the ranges $v_{x1} \to v_{x1} + dv_{x1}$, $v_{y1} \to v_{y1} +
dv_{y1}$, $v_{z1} \to v_{z1} + dv_{z1}$ is

$$
p(v_{x1}, v_{y1}, v_{z1}) \, dv_{x1} \, dv_{y1} \, dv_{z1} \equiv \phi(v_{x1}) \, \phi(v_{y1}) \, \phi(v_{z1}) \, dv_{x1} \, dv_{y1} \, dv_{z1}
$$
where \( v_1^2 = v_{1x}^2 + v_{1y}^2 + v_{1z}^2 \) and we have assumed the velocity distribution to be isotropic. An expression completely analogous to (A.3) holds for grain 2. Following Margenau & Murphy (1956), it may be shown that the probability of grain 1 having an \( x \)-component of velocity in the range \( v_{1x} \rightarrow v_{1x} + dv_{1x} \) and grain 2 having an \( x \)-component of velocity in the range \( v_{2x} \rightarrow v_{2x} + dv_{2x} \) is

\[
\phi(v_{1x}) \phi(v_{2x}) \, dv_{1x} \, dv_{2x} = \frac{H}{\pi^2} e^{-H^2 v^2} \, dv_x
\]

(A.4)

where

\[
\frac{1}{H^2} = \frac{1}{h_1^2} + \frac{1}{h_2^2} = \frac{2}{\hbar^2}
\]

(A.5)

when \( h_1 = h_2 \equiv h \); \( v_x = v_{1x} - v_{2x} \) is the relative \( x \)-component of velocity of the two grains. Analogous expressions hold for the \( y \)- and \( z \)-components of velocity. Thus, the probability of finding the velocity components of the grains within the ranges specified above is

\[
p(v_{1x}, v_{1y}, v_{1z}) \, p(v_{2x}, v_{2y}, v_{2z}) \, dv_{1x} \, dv_{1y} \, dv_{1z} = P(v_x, v_y, v_z) \, dv_x \, dv_y \, dv_z
\]

(A.6)

where \( \mathbf{v} = \mathbf{v}_1 - \mathbf{v}_2 \) is the relative velocity of the grains 1 and 2. As the distributions are isotropic,

\[
dv_x \, dv_y \, dv_z = 4\pi v^2 \, dv
\]

(A.7)

Defining

\[
P(v) \equiv 4\pi P(v_x, v_y, v_z)
\]

\[
P(v) = 4\pi \left( \frac{H}{\pi^2} \right)^3 e^{-H^2 v^2}
\]

(A.8)

we have the overall normalization condition

\[
\int_0^\infty P(v) v^2 \, dv = 1
\]

(A.9)

The rate coefficient for coagulation in grain–grain collisions is

\[
\langle \sigma v \rangle = 4\pi a_g^2 \int_0^{v_{\text{crit}}} v P(v) v^2 \, dv
\]

(A.10)

where \( \sigma = 4\pi a_g^2 \) is the cross section for collisions between identical grains; this is the expression for the geometrical cross section, assuming the grains to be spherical, which minimizes their surface area (and effective cross section) for a given volume. Clearly, non-spherical grains would have a larger cross section. The neglect of the Coulomb and polarization potentials, which arise when at least part of the population of grains is charged, may be seen to be justified as follows.

The grain population consists of neutral and singly charged grains; of the latter, negatively charged grains are by far the most abundant. Consider the long-range Coulomb interaction between two grains, each with a single negative charge; this repulsive potential is given by

\[
V_{\text{Coul}} = \frac{e^2}{r},
\]

where \( r \) is the separation of the grain centres; \( V_{\text{Coul}} \) has a maximum value of \( e^2/(2a_g) \), when the grains are in contact. The kinetic energy of a grain, in the centre of mass system, is \( m_g v^2/2 \); the critical speed, \( v_{\text{crit}} \), when the grains are in contact, is

\[
\frac{\langle \sigma \rangle v}{m_g} = \frac{4\pi a_g^2}{2\rho_g}
\]

\[
\approx \frac{4\pi a_g^2}{2\rho_g}
\]

where \( \rho_g \) is the density of the grain. The critical speed, \( v_{\text{crit}} \), is affected significantly by the Coulomb interaction. Taking \( a_g = 0.05 \mu m \), which is the minimum value of \( a_g \), the mass of a grain is \( m_g/2 \) is the reduced mass, for collisions between identical grains; \( v_{\text{crit}} \) is the relative collision speed. Taking \( a_g = 0.05 \mu m \), which is the minimum value of \( a_g \), the mass of a grain is \( m_g/2 \) is the reduced mass, for collisions between identical grains; \( v_{\text{crit}} \) is the relative collision speed. Taking \( a_g = 0.05 \mu m \), which is the minimum value of \( a_g \), the mass of a grain is

\[
v_{\text{crit}} \approx \frac{3}{2\pi^2 a_g^2} \left( \frac{e^2}{2\rho_g} \right)^{1/2}
\]

\[
\approx \frac{3}{2\pi^2 a_g^2} \left( \frac{e^2}{2\rho_g} \right)^{1/2}
\]

where \( a_g \) is the polarizability of a grain of radius \( a_g \). Taking into account this interaction would tend to enhance the cross section for coagulation of a neutral and a charged grain; but arguments analogous to those immediately above show that the effect would be negligible for the velocity distribution that we have adopted.

Following Chokshi et al. (1993), we assume that the grains stick (coagulate) if the relative collision speed \( v \) \( \leq v_{\text{crit}} \). The critical speed, \( v_{\text{crit}} \), is

\[
\sigma \sim a_g^{-5/6}
\]

\[
\sim a_g^{-5/6}
\]

according to Chokshi et al. (1993); the constant of proportionality depends on the grain composition. Using (A.8), the integral in equation (A.10) can be evaluated, yielding

\[
\langle \sigma v \rangle = \sigma \left( \frac{2}{\pi^{1/2}} \right)^{3/2} \Delta v \left[ 1 + 2 \ln 2 + \frac{2}{2} \left( \frac{v_{\text{crit}}}{\Delta v} \right)^2 \right] \exp \left[ -2 \ln 2 + \frac{2}{2} \left( \frac{v_{\text{crit}}}{\Delta v} \right)^2 \right]
\]

\[
\langle \sigma v \rangle = \sigma \left( \frac{2}{\pi^{1/2}} \right)^{3/2} \Delta v \left[ 1 + 2 \ln 2 + \frac{2}{2} \left( \frac{v_{\text{crit}}}{\Delta v} \right)^2 \right] \exp \left[ -2 \ln 2 + \frac{2}{2} \left( \frac{v_{\text{crit}}}{\Delta v} \right)^2 \right]
\]
= \sigma \cdot 0.9584 \Delta v \left(1 - \frac{\Delta v}{2} \left(1 + 1.3863 \left(\frac{v_{\text{crit}}}{\Delta v}\right)^2\right) \exp \left[-1.3863 \left(\frac{v_{\text{crit}}}{\Delta v}\right)^2\right]\right)

where we have substituted $H^2 = h^2/2$ and defined

$$h^2 = \frac{4 \ln 2}{(\Delta v)^2} \quad (A.12)$$

where $\Delta v$ is the FWHM of the Gaussian distributions (A.1) and (A.3) above, i.e. the width of the grain velocity distribution.

Using equation (A.11), it may be shown that, when $v_{\text{crit}} \ll \Delta v$,

$$\langle \sigma v \rangle \approx \frac{\pi a}{\sqrt{2}} \frac{v_{\text{crit}}^4}{(\Delta v)^3} \approx 0.9209 \left(\frac{v_{\text{crit}}}{\Delta v}\right)^3 \sigma v_{\text{crit}}$$

whereas, when $v_{\text{crit}} >> \Delta v$,

$$\langle \sigma v \rangle \approx 0.9584 \sigma \Delta v$$

In practice, $v_{\text{crit}}$ and $\Delta v$ are comparable, and the exact expression (A.11) was used to calculate the coagulation rate coefficient.

In Fig. A.1 is plotted the variation of the rate coefficient, $\langle \sigma v \rangle$, with the turbulent width, $\Delta v$, for $a_g = 0.05 ~\mu m$. Also shown in the Figure are fractions of the adiabatic sound speed, $c_s$ (evaluated at $T = 10$ K). The linear dependence of $\langle \sigma v \rangle$ on $\Delta v$, in the limit $\Delta v << v_{\text{crit}}$, is evident in this Figure. The rate coefficient has a maximum near $\Delta v = c_s/4$, for the adopted value of $a_g$ and assuming that $v_{\text{crit}}(a_g) = 0.4 ~a_g^{-5/6}$ (Poppe & Blum 1997; broken curve in Fig. A.1); turbulent widths much in excess of or much below this value result in negligible coagulation.

### Appendix B: The initial value of $a_g$

Here we demonstrate that the value of $a_g$ required to reproduce a given value of $n_g \pi a_g^2$ depends only on the adopted size distribution and its limits, and not on the density of the grain material nor the dust:gas mass ratio. The grain size distribution is taken from Mathis et al. (1977):

$$dn_g \propto a_g^{-3.5} da_g$$

Let $a_M$ be the upper limit to the distribution and $a_m$ be the lower limit. Then, following Le Bourlot et al. (1995), the mean grain opacity is given by

$$\langle n_g \sigma_g \rangle = \frac{3}{4 \eta} \frac{\rho_a}{M} \left(a_m^{-0.5} - a_m^{-0.5}\right) \quad (B.1)$$

where

$$\eta = \frac{1.4 \rho_H G}{\rho_g} \quad (B.2)$$

Fig. 1. The fractional abundances of (a) selected neutrals and (b) the major ions, as functions of the evolution time, $t$. Results are shown for the limiting case of no coagulation and assuming that the timescale for collapse is determined by the free–fall time, $\tau_{ff}$. The corresponding density profile, $n_H(t)$, is plotted in panel (c).
Fig. 2. The fractional abundances of the exemplary neutrals, $N_2$ and CO, as functions of the gas density, $n_H$. Results are shown (a) for the limiting case of no coagulation, with the timescale for collapse determined by either the free–fall time, $\tau_{\text{ff}}$, or the ambipolar diffusion time, $\tau_{\text{ad}}$; (b) including coagulation, with $v_{\text{crit}}(a_g) = 0.1 \ a_g^{-5/6}$ (Chokshi et al. 1993; full curves) or $v_{\text{crit}}(a_g) = 0.4 \ a_g^{-5/6}$ (Poppe & Blum 1997; broken curves). $\Delta v = c_s/4$, where $\Delta v$ is the turbulent width and $c_s$ is the adiabatic sound speed. The timescale for collapse is determined by the free–fall time, $\tau_{\text{ff}}$.

Fig. 3. The variation of the grain radius, $a_g$, as a function of the gas density. Results are shown for the limiting case of no coagulation ($v_{\text{crit}} = 0$) and for $v_{\text{crit}}(a_g) = 0.1 \ a_g^{-5/6}$ (Chokshi et al. 1993) and $v_{\text{crit}}(a_g) = 0.4 \ a_g^{-5/6}$ (Poppe & Blum 1997); $\Delta v = c_s/4$, where $\Delta v$ is the turbulent width and $c_s$ is the adiabatic sound speed. The timescale for collapse is determined by the free–fall time, $\tau_{\text{ff}}$. 
Fig. 4. The fractional abundances of the specified gas–phase ions and the electrons, as functions of the gas density. Results are shown for (a) the limiting case of no coagulation \( (v_{\text{crit}} = 0) \), (b) \( v_{\text{crit}}(a_g) = 0.1 \ a_g^{-5/6} \) [equation (9); Chokshi et al. (1993)], and (c) \( v_{\text{crit}}(a_g) = 0.4 \ a_g^{-5/6} \) (Poppe & Blum 1997); \( \Delta v = c_s/4 \), where \( \Delta v \) is the turbulent width and \( c_s \) is the adiabatic sound speed. The results in panel (d) were obtained on reducing the value of the sticking coefficient for molecular nitrogen to \( S(N_2) = 0.1 \) and should be compared with those in panel (c), where \( S(N_2) = 1 \). In all cases, the timescale for collapse is determined by the free–fall time, \( \tau_{\text{ff}} \).

Fig. 5. (a) The fraction and (b) the opacity per H nucleus, \( (n_g / n_H) \pi a_g^2 \), of negatively charged grains, as functions of the gas density, \( n_H \). Results are shown for the limiting case of no coagulation \( (v_{\text{crit}} = 0) \), for \( v_{\text{crit}}(a_g) = 0.1 \ a_g^{-5/6} \) [equation (9); Chokshi et al. (1993)], and for \( v_{\text{crit}}(a_g) = 0.4 \ a_g^{-5/6} \) (Poppe & Blum 1997); \( \Delta v = c_s/4 \), where \( \Delta v \) is the turbulent width and \( c_s \) is the adiabatic sound speed. The timescale for collapse is determined by the free–fall time, \( \tau_{\text{ff}} \).
Fig. 6. A comparison of the fractional abundances of the principal ions, (a) as computed by Walmsley et al. (2004), assuming steady-state, and (b) as predicted by the present dynamical model; $a_g = 0.05 \, \mu m$ and, in this case only, $\zeta = 3 \times 10^{-17} \, s^{-1}$, in order to be able to compare directly with Walmsley et al. (2004). ["H$_3^+$" denotes $n(H_3^+)+n(H_2D^+)+n(HD_2^+)+n(D_3^+).]

Fig. A.1. The variation of the rate coefficient for coagulation, $\langle \sigma v \rangle$, with the turbulent width, $\Delta v$, for $a_g = 0.05 \, \mu m$ and $v_{\text{crit}}(a_g) = 0.1 \, a_g^{-5/6}$ (Chokshi et al. 1993; full curve) or $v_{\text{crit}}(a_g) = 0.4 \, a_g^{-5/6}$ (Poppe & Blum 1997; broken curve). Also shown are fractions of the adiabatic sound speed, $c_s$, evaluated at $T = 10 \, K$. 

$n(X)/n_H$ (cm$^{-3}$)
