Effects of Long-Term Nitrogen Dioxide Exposure on Rat Lung: Morphological Observations

by Kentaro Kubota,* Masataka Murakami,* Shinji Takenaka,* Kiyoyuki Kawai,† and Hiroko Kyono†

Rats continuously exposed to NO₂ at 0.04, 0.4, and 4.0 ppm for as long as 27 months were submitted to morphological observation and electronmicroscopic morphometry of the lung.

At 4 ppm exposure for 9 months, bronchial epithelium showed typical proliferation, which progressed further at 18 months. At this stage, proliferation of type II alveolar epithelium and edematous extension of interstitial tissue were evident and yielded fibrosis at 27 months.

At 0.4 ppm, morphological changes in 18-month specimens were still ambiguous, although a tendency toward epithelial changes, as well as interstitial edema of the alveolar wall, was noticed under the electron microscope. Slight but definite alteration of the epithelium became evident after 27 months. At 0.04 ppm there were no remarkable changes throughout the entire exposure period.

The morphometry revealed concentration- and duration-dependent increases in arithmetic mean thickness (AMT) of the alveolar wall. At 4 ppm, increase of AMT started as early as 9 months, became significant at 18 months, and showed a slight decrease at 27 months. This decrease was interpreted as a recovery of alveolar epithelium and decreased amount of septal edema, which in turn led to fibrosis. At 0.4 ppm, a slight increase of AMT started at 18 months and extended significantly in 27 months. A similar but insignificant tendency was found even at 0.04 ppm.

The morphological alterations were parallel to the concentration and duration of exposure. These findings suggested that an intensive study should be conducted to confirm whether alterations were due to prolonged exposure and/or due to elevated sensitivity of the aged lung.

Introduction

When animals were exposed to high concentrations of NO₂, they died due to hemorrhage, edema, and cell infiltration in the lung. The study of long-term NO₂ exposure is important for elucidating the effects on humans exposed to polluting agents in the atmosphere (1,2).

There are a number of reports, including a series of works by Freeman and his colleagues, concerning the morphological effects on the lungs of relatively low concentrations of NO₂ for 1 month or longer (3–11). The common fundamental lesions in these studies are found mainly at both the airways and bronchopulmonary junction, and include: uneven arrangement, shortening, or loss of cilia in ciliated epithelium, and hypertrophy, hyperplasia, and hypersecretion of nonciliated epithelium; fibrous thickening of connective tissue at the terminal end of air tracts; and damage and desquamation of type I epithelial cells and subsequent proliferative response of type II epithelial cells. Extremely high levels of NO₂ exposure induced emphysema (3–6,8,10,11), and the pathological findings in the lung from this disease were reported (12–14). There were, however, very few reports on effects of NO₂ at a low level over a lifetime under well-controlled experimental conditions. Moreover, the usual descriptive pathology is insufficient to evaluate the degree of such mild or focal lesions caused by ambient levels of NO₂ concentration and to compare studies.

The experimental methods used in this study included not only ordinary light and electron transmission microscopy, but also electron microscopic morphometry as described by Weibel et al. (15,16) to obtain quantitative data on pathological findings (17–21). Pathological changes were evaluated objectively.

Materials and Methods

Experimental Conditions

Animals. Two-month-old male rats of JCL/Wistar strain (SPF) were exposed continuously (24 hr/day) to three concentration levels of NO₂ (0.04 ± 0.008, 0.40
± 0.04, and 4.0 ± 0.4 ppm) for 9, 18, and 27 months. One group served as a control. The exposure procedure and the time course of the survival of exposed animals in the present study were reported in detail previously by Sagai et al. (22). Three or four animals selected randomly from each group were used for morphological observation and electron microscopic morphometry.

Serological Examination. Serological testing such as complement binding response was conducted for the serum of all experimental rats at the time of the experiment in order to detect any trace of lung infection. A few animals showed an increase of antibody response to B. bronchoseptica and Sendai virus; the positive ratios for all experimental animals were 7.9 and 1.2%, respectively. Nevertheless, pathological changes induced by infection were not observed in the lungs of any animals. The indices of electron microscopic morphometry of the lungs of all control animals measured at each exposure time were within the normal range. These findings confirmed that no pathogenic microbes, including those causing respiratory infection, altered the lungs of rats used in this study.

Morphometry Procedure

Tissue Preparation. The thorax was opened under anesthesia with sodium pentobarbital. Ice-cold isotonic glutaraldehyde fixative (1.5% glutaraldehyde in 0.088 M cacodylate buffer at pH 7.4 with 1.5% dextran, osmolarity 330 mOsm) was dropped from a height of 20 cm and was instilled through a needle inserted in the trachea in situ, and at the same time depletion was accomplished by cutting the femoral artery. Subsequently, the lung was filled with the fixative and fully re-enlarged inside the opened thorax. When the inserted needle was withdrawn, the excess fixative overflowed, leaving the lung fixed at about 50% volume level of total lung capacity. Vertical slices of about 2 mm thickness through the hilar region of the lung were cut and fixed overnight in the same fixative. The slice was cut into 10 to 15 pieces and postfixed with 1% OsO₄ solution for 1 hr. Dehydration began with 70% alcohol; the tissue was then passed through propylene oxide and embedded in Epon 812.

The remaining portions of lung tissue were prepared
as paraffin-embedded sections for light microscopic observation.

**Sampling for Electron Microscopic Morphometry.** Lung sections from two rats of each group were used for electron microscopic morphometry. Sections of 1 μm thickness were cut from pieces of lung chosen randomly, stained with toluidine blue, and screened under a light microscope. Four blocks containing lung parenchyma wide enough for morphometric purposes were chosen. Thin sections were cut with a diamond knife, transferred onto the supporting grid (Maxtaform H2), and stained with uranyl acetate and lead citrate.

As these sections covered 15 to 20 spaces of the supporting grid, the lung areas were systematically recorded on electron micrographs at initial magnification of ×2000 from the consecutive fields of grid corners, and 10 grid corners were used for counting.

Alveoli adjacent to the ends of the terminal bronchioles and to the small blood vessels were excluded from the counts, and alveoli at the more peripheral regions were subjected to measurement.

**Morphometry.** Electron micrographs were projected to a final magnification of ×8000 on a screen by the coherent multipurpose test system described by Weibel et al. (15), and the arithmetic mean thickness of the air-blood barrier (AMT) was measured. AMT was measured for 80 micrographs per group, consisting of 10 micrographs from four sections each of two experimental animals.

AMT was expressed without any correction for shrinkage or elongation factors in the course of sample preparation because the procedure used was the same for all groups observed (20).

**Volume Density of Alveolar Wall Components (VdAWT).** Volume density of each alveolar wall compartmental component was counted by the point counting method. A test sheet containing 293 cross points was placed on each micrograph and the number of points distributed on each component counted. Student’s t-test for the mean of 80 micrographs and χ²-test for the pooled sum of total points on each component of all 80 micrographs were applied to evaluate statistical significance.

**Mean Number of Alveolar Cells and the Volume Density per Cell.** A differential cell count was made of all cells of the alveolar wall with visible nuclei in 80 micrographs in each group. Comparison of cell numbers was made using the sum of cells per group appearing in a unit area of section used. Volume density per cell was calculated as the number of points per mean number of cells with visible nuclei found in the measured area.

**Results**

4 ppm NO₂

Typical morphological changes appeared in the lungs of rats exposed to NO₂ at 4 ppm for 9 months. The lesions were hypertrophy and hyperplasia of bronchial
FIGURE 4. Tissue from a rat after exposure to 4 ppm NO$_2$ for 27 months. Proximal region of alveolar duct where the last cuboidal cell of respiratory bronchiole is seen at upper right (→). Note greatly thickened basement membrane (BM), as well as increase of collagen fibers (Cl). Osmiophilic inclusion appeared in an interstitial cell (←).

FIGURE 5. Alveolar wall from a 20-month-old rat (control for 18-month exposure). Note smooth surface of air-blood barrier and delicate thin layer of basement membrane.
mucosa, and thickening of walls in the area through the bronchopulmonary junction to the alveolar duct, with cell infiltration and increase of Clara cells. These findings have already been reported at various concentrations of NO\textsubscript{2} and are thought to be typical of NO\textsubscript{2} exposure. The lesions progressed according to the prolongation of exposure (Figs. 1 and 2).

After 27 months of exposure, morphological changes of bronchiolar mucosa remained on the same level as at 18 months; however, the lesions in the area from bronchopulmonary junction to the proximal alveoli progressed more severely, and the interstitial fibrosis and hyperplasia of epithelium seemed to progress steadily. Pathological changes in walls of the more peripheral alveoli were obscure, and the alveolar structure was maintained very well until 27 months of exposure, and no emphysema developed.

Electron microscopic observation proved that various components of alveolar wall changed depending on NO\textsubscript{2} concentration and exposure periods. The following findings were observed: hypertrophy of type I and type II cells, increase of cellular organelle, increase of homogeneous matrix of interstitial tissue, polymorphic change of interstitial cells, increase of collagen fibers in the interstitium, and heterogenity of endothelium in the vasa. Intracellular edema, degeneration, and necrosis were seldom found. Appearance of macrophages and infiltration of inflammatory cells into the alveolar wall were not conspicuous throughout the inhalation period (Figs. 3–7).

Findings such as those described are too qualitative and local to give an understanding of to what extent and how the lesion developed. Morphometric quantification helps to elucidate the time-course image of pathological change and the concentration-dependent change clearly, in addition to facilitating an understanding of qualitative morphological alterations.

The time course of alveolar lesions seemed to show two phases: the first phase was from 9 to 18 months of exposure, and the second phase was from 18 to 27 months. Various kinds of tissue components increased in the first phase, but decreased in the second phase.

**Phase 1.** At 9 months, a decrease in cell number (Fig. 8B) and an increase in cell volume of type I epithelium (Fig. 8C) were observed. As a result of these changes, the comparative ratio of type II cell number to type I cell number increased (Fig. 9).

At 18 months, an increase of cell number (Fig. 10B)
and volume of type II cells (Fig. 10C), an increase of interstitium (Fig. 11), and a change in the endothelium were noticed. From these findings, it was assumed that at 4 ppm NO₂ exposure, the change of alveolar walls began as a change in type I cells and very slowly extended to type II cells and other cellular components. The lesions of bronchial mucosa appeared in the early stage of exposure, and the change of distal alveoli followed.

**Phase 2.** Electron microscopy showed evidence of recovery of the alveolar epithelium during months 18 to 27. However, the total volume of interstitial tissue, including either cellular or noncellular components, decreased (Fig. 11), and electron micrographs indicated that interstitial edema was replaced by collagen fibers (Fig. 12A,B).

The *de novo* synthesis of fiber in interstitium did not always mean complete recovery, and the possibility of functional disturbance was also suggested. Accordingly, the lesions of the alveolar wall were progressing to the next pathological phase during this period.

It is evident that the lesions of the alveolar wall progressed very slowly under long-term exposure to 4 ppm NO₂. Some of the lesions of the alveolar epithelium appeared to be repaired, whereas other lesions of the interstitium were always progressive.

**0.4 ppm**

The lesion was generally milder than 4 ppm, and the initial time was delayed. The morphological change of bronchiolar epithelium, bronchopulmonary junction, and alveolar walls was detectable at 18 months by electron microscopy (Fig. 13), but no definite morphological change was discerned by light microscopy until month 27.

As evidenced by morphometric indices, AMT (Table 1, Fig. 14A,B) and various indicators concerning interstitium (Fig. 11) increased according to exposure time. Interestingly, alveolar epithelium showed a tendency toward recovery at 27 months in the same pattern as at the 4 ppm level (Figs. 8–10).

The lesions at the 0.4 ppm level corresponding to the first phase at 4 ppm progressed very slowly, and the degree of the alteration was emphasized with time, though the degree of alteration was slight. After a fully prolonged exposure period, the typical pathological lesion was seen.
0.04 ppm

The difference of morphological findings between the control group and the 0.04 ppm-exposed group from 9 to 27 months could not be determined by light and electron microscopy. However, morphometric indices showing the tendency of increment of AMT (Table 1, Fig. 14A,B), interstitial components (Figs. 11 and 15), and the pattern of variation of alveolar type II cells (Fig. 10) depending on exposure period suggested that reactions similar to those at the 0.4 ppm level were expressed in a milder form.

Discussion

Effects of Chronic NO₂ Exposure

Morphological findings in rats chronically exposed to NO₂ were summarized in the “Introduction.” The character of lesions, particularly of 4 ppm groups, was the same as reported in other studies (3-5,8,10). At the 4 ppm level or lower, we could not find any sign of inflammatory cell infiltration or enlargement of the lymphatic system, or emphysema.

Freeman et al. (5) and Stephens et al. (7,23) indicated that typical lesions occurred in rats exposed to 2 ppm NO₂ for 2 years. Compared with these results (5,7,23), the lesions induced by 4 ppm were more severe. Furiosi et al. (24) also found hypertrophy of bronchial epithelia in rats exposed to 2 ppm for 425 days. Evans et al. (10) reported that exposure to 1 to 2 ppm for life clearly induced lesions of the epithelial lining of the airway, although these lesions were not as severe.

Little work has been done on the effects of chronic exposure to 2 ppm or less. Wagner et al. (25) reported that they could not gain any positive results from several species of rodents, including rats and mice, exposed intermittently to 1 ppm for 6 hr/day or 5 days/week for 18 months. Their histological description also included some inflammatory changes common to both experimental and control groups. Exposure to 0.8 ppm for 33 months occasionally induced slight morphological alterations in the small bronchiolar epithelia, but the result was evaluated to be negative on the whole (4). Blair (26) observed the emphysematous hyperextension of alveoli and the thickening of alveolar wall in the mouse exposed to 0.5 ppm for as long as 12 months. However,
lack of the typical lesion induced by NO₂, appearance of pneumonia, and inflammatory changes require prudent interpretation.

Port et al. (27) exposed mice to 0.1 ppm NO₂ with a 2 hr peak of 1 ppm NO₂ daily for 6 months. The emphysematous changes in the lung were dilated respiratory bronchioles and alveolar ducts. Tissue destruction appeared and numerous broken and/or stretched alveolar septa were seen with the scanning electron microscope. Yamamoto et al. (28) exposed rats to 0.5 ppm and 1.0 ppm of NO₂ for 7 months. Changes in cilia included swelling (0.5 ppm) and a decrease in number, or loss (1.0 ppm). They also observed hyperplasia of type II cells (0.5 and 1.0 ppm), decrease in number of lamellar bodies in type II cells (1.0 ppm), and interstitial edema of alveolar walls (1.0 ppm).

In the present study, at 0.4 ppm, the slight degree of morphological alterations appeared later than 18 months and extended to the typical lesion at 27 months. From these results, it was assumed that NO₂ exposure to 0.4 ppm or more should certainly induce definite injury to the lung tissue under long enough exposure periods.

Initial Lesions

In addition to long-term exposure at low levels, there were some reports about lesions induced by low level exposure for 2 or 3 months. Nakajima et al. (29) noticed the proliferation of the terminal bronchiolar epithelia and edematous swelling of alveolar epithelia in the lungs of mice exposed to 0.5 to 0.8 ppm for 1 to 1.5 months. Crapo et al. (30) exposed rats to 2 ppm NO₂ for 23 hr/day with twice daily spikes of 6 ppm for 30 min each for 6 weeks. Both the increased number and increased thickness of alveolar type I cells were demonstrated morphometrically. A 10 to 15% increase was found in both interstitial cells and interstitial matrix. The number of alveolar type II cells increased by about 40%.

Kyono and Kawai (19) clearly detected the typical lesions in lungs of rats exposed to 3 ppm or more for 1 month and the slight morphological alterations of bronchial epithelia and thickening of the alveolar wall at 0.5 ppm.

Terada et al. (31) exposed rats to 0.3 to 8 ppm NO₂.

Figure 11. Total volume of interstitium in NO₂-exposed rats. (☐ = 9-month exposed; ☐ = 18-month exposed; ☐ = 27-month exposed.) The upper portion of the bar represents noncellular elements; the lower portion represents cellular elements.
FIGURE 12. Alveolar wall from the peripheral alveolar region of a rat that received 4 ppm NO₂ for 27 months. (A) An area of interstitial lesion with extraordinary varied thickness of basement membrane (BM) and deposition of very large collagen fibrils (Cl). Greatly thickened air-blood barrier and reduced size of capillary lumen (Ca) are remarkable. (B) Note stellate appearance of some of the collagen fibrils (→) in cross section. Collagen fibrils about two to three times the diameter of normal size fibrils (300 Å) can be seen. (F) fibroblast; (Ca) capillary lumen.
for 1 week to 18 months. They reported that the lesions in the middle-sized bronchi appeared at 1 week at the 4 or 8 ppm level, at 3 weeks at 2 ppm, and at 4 weeks at 0.5 ppm NO₂. The locus of the lesion extended toward the distal airways as exposure time was prolonged.

These positive results from low-level exposure for a short term suggest that the response of the lung tissue at even the 0.5 ppm level should appear at a relatively early time after exposure.

Table 1. Arithmetic mean alveolar wall thickness in rats exposed long term to NO₂.*

| NO₂ concentration | 9 months | 18 months | 27 months |
|-------------------|----------|-----------|-----------|
| Control           | 1.41 ± 0.15 (100) | 1.29 ± 0.13 (100) | 1.33 ± 0.16 (100) |
| 0.04 ppm          | 1.43 ± 0.14 (103.6) | 1.33 ± 0.15 (103.6) | 1.55 ± 0.18 (116.5) |
| 0.4 ppm           | 1.39 ± 0.14 (98.2) | 1.44 ± 0.16 (111.9) | 1.82 ± 0.19* (136.7) |
| 4.0 ppm           | 1.50 ± 0.18 (105.8) | 1.71 ± 0.16* (133.1) | 1.57 ± 0.20 (118.0) |

*Values for mean alveolar wall thickness are expressed as μm ± SE. Numbers in the parentheses are percent of the corresponding control values.

Statistically significant to the corresponding control values (p < 0.001).

Recovery of Lesions

In our second experiment (31), rats were exposed to 0.04 to 0.4 ppm for 3 to 18 months. The very weak responses, i.e., reduction of the number of extruded cell and mild hypertrophy of the terminal bronchiolar lining, continued throughout the exposure periods. The responses that appeared in the lung at 3 or 18 months were stronger than those at 6 or 9 months. The responses after 6 or 9 months seemed to be weaker than those at 3 months; therefore, the degree of respiratory lesions in these periods did not correlate with the total cumulative dose of concentration and time. Lesions caused directly by NO₂ concentration were observed, as well as lesions due to the aging of animals. Animals maintained adequate level of responses, which were affected by acquired tolerance under continuous low doses of exposure.

Terada et al. (31) reported the typical mild alterations of the epithelium in the middle to terminal region of the bronchial tree of rats at 0.5 ppm level after 18 months in a chronic inhalation experiment of NO₂ ranging from 0.3 to 1.0 ppm. Their results show a weak positive response, but not a definite NO₂-caused lesions at 0.3 ppm at 3 or 18 months, although the alterations became weaker after 6 to 12 months. Our findings are fundamentally in accord with these results.
The response process of alveolar epithelium under the continuous long-term exposure to NO₂ is a good example for analyzing the passage of lesions induced by NO₂. Impaired type I alveolar epithelial cells were necrotized, desquamated, and replaced by the regenerated type II cells shortly after the onset of NO₂ exposure (9,10,33–36). In long-term exposure at 2 ppm and 0.5 ppm (37), the same phenomena in the alveoli were reported (8). It is accepted that once these mechanisms have started, the newly repaired epithelium shows tolerance to NO₂ (10).

In our present long-term study, the same phenomena seemed to occur, and transformation of proliferated type II cells into type I cells continued very gradually during 27 months. On the other hand, the lesions of the bronchopulmonary junction and of alveolar interstitium were progressive, and thus accumulated gradually with prolonged exposure.

The results of chronic exposure clearly indicate that the degrees of respiratory lesions induced by NO₂ were parallel to the concentration of NO₂ and progressed according to prolongation of exposure.

**Recovery at NO₂ Exposure of 0.4 ppm or Less.** Information was rarely available concerning the effects of NO₂ on animals exposed continuously for a long time at a concentration under 0.4 ppm. Hasegawa et al. (38) found changes of some biochemical indices such as the increase of blood glutathione level in rats exposed to 0.12 ppm for 1 month. Using part of the same specimens, Kyono and Kawai (19) observed a trend of increase in morphometric indices such as AMT. As the same result was obtained when the experiment was repeated, a completely negative effect of NO₂ at 0.12 ppm was not excluded. If the values of these morphometric indices increased as exposure time increased, definite lesions would be expected.

The tendency of gradual increase of morphometric indices found at 0.04 ppm level in the present experiment was insignificant; however, it should be noted that the trend was also observed in 0.4 or 0.12 ppm level. This trend should be considered and investigated much more intensively.

**Aging and Lesions.** One of the important results in the present study was the relationship between the progress of lesions and the aging of animals. Between 18 and 27 months, the lesions at the 0.4 ppm level became distinct, and some of the morphometric indices at 0.04 ppm increased similarly.

Cabral-Anderson et al. (42) and Evans et al. (35) studied the relationship between aging and the progression of lung injuries induced by NO₂ exposure. Aged rats were more damaged than younger rats because of the delayed onset of repair function to the initial injury; however, older rats acquired similar tolerance to NO₂.
after the repair system was activated. The lung response of 25-month-old rats was as high as that of 1-month-old rats.

Age-related differences in sensitivity to NO\textsubscript{2} have been noted recently (39,40). It has been reported that lung impairment in neonatal mice and rats is slight, while sensitivity increases in young adult animals (41). Also, the onset of cell repair is slower in older rats (35,42). However, little is known about the relationship between the age of animals and effects on the lung of lower concentrations of NO\textsubscript{2} (<1 ppm) and NO\textsubscript{2} at ambient air pollution levels.

Kyono and Kawai (19) performed electron microscopic morphometry on the alveolar wall (excluding the alveolar ducts) on the lungs of 1, 3, 12, and 21-month-old rats exposed to 0.1 to 10 ppm NO\textsubscript{2} continuously for 1 month. The response of lung tissue to NO\textsubscript{2} exposure showed age-related differences at exposure onset. Based on the morphometric index, the reactivity was highest in the 1-month-old and decreased in order in the 3- and 12-month-old, but increased again in the 21-month-old rats. They reported that volume density of alveolar wall tissue and surface area of alveoli and capillary lumen of the groups (except for 12-month-old rats exposed to 0.1 and 0.5 ppm for 1 month) differed significantly from control groups, which meant the increase of AMT.

Judging from these findings, aging probably has a close relationship to susceptibility to NO\textsubscript{2} in rats. Middle-aged rats generally responded weakly to NO\textsubscript{2}, but older rats responded strongly. It is fully expected that the lesions induced by low concentrations of NO\textsubscript{2} become stronger and that qualitative alterations may occur after 18 months due to the modified susceptibility with aging.

Some changes in connective tissue in lung and slight enlargement of alveoli were noted in rats after chronic exposure to NO\textsubscript{2} (23,43). How and to what extent does the continuous exposure to low level of NO\textsubscript{2} accelerate the age-dependent thickening or fibrogenesis of alveolar wall? These problems as a causative factor of emphysema (44) in animals with a far longer life-span than rats remains to be determined.

The authors thank Fujio Shimizu, Yasuko K. Yamada, Junzo Sae-gusa, and Takahiko Harada for their valuable help and discussion during the experiments. Also, thanks are due to Ryoko Kawamura, Yoshiko Sawada, Satoko Shimizu, Yoshiko Shinbo, and Kazumi Kano for their technical assistance.
