**Undifferentiated Induced Pluripotent Stem Cells as a Genetic Model for Nonalcoholic Fatty Liver Disease**

Patient-derived induced pluripotent stem cells (iPSCs) have been transformational in biomedical research for their ability to differentiate into any cell type while retaining the genetic information of the donor individual, for example iPSC-derived hepatocyte-like cells (iPSC-Heps) for studies of nonalcoholic fatty liver disease (NAFLD). However, differentiation protocols are time-intensive, use costly reagents, require highly specialized training, and can result in heterogeneous cultures that are limited in number. Thus, iPSC-Heps are poorly suited for studies of genetic variation that require scalability and reproducibility. In contrast, iPSCs exhibit self-renewal, can be cryopreserved, have standardized and robust protocols available for their generation and culturing, and are substantially less expensive to produce. We tested whether iPSCs in their undifferentiated state may be informative to model genetic factors underlying NAFLD. NAFLD is initiated by hepatic steatosis, often attributed to excess synthesis, retention, or uptake of fatty acids by the liver, where they are stored as triglycerides within lipid droplets. As nearly all cells can take up fatty acids, synthesize triglycerides, and create lipid droplets, we sought to determine whether iPSCs could model fatty acid-induced lipid accumulation.

Authenticated iPSCs (Supplementary Table 1) were previously described. We confirmed that a representative iPSC accumulates intracellular lipids in response to 24-hour oleate challenge in a dose dependent manner, with lipids detected by 2 neutral lipid stains (Nile Red and LipidTox Red) and through Simulated Raman Spectroscopy, a highly specific detection method for unlabeled triglycerides (Figure 1, A–B). To improve quantitation accuracy, we developed a flow cytometry-based assay (Figure 1, C), resulting in highly reproducible measures (Figure 1, D), which confirmed that oleate treatment increased intracellular lipids in cell lines from 30 donors (2.0 ± 0.11 fold mean ± standard error; P = 4.0e-10 (Figure 1, E; Supplementary Table 2).

We next compared the degree of oleate-induced lipid accumulation in iPSCs from 8 donors both in their

**Figure 1.** iPSCs accumulate intracellular lipids when challenged with oleate. (A) Images taken at 100× magnification of an iPSC line challenged for 24 hours with (0–100 μM) sodium oleate conjugated to bovine serum albumin (BSA). Cells were stained with 100 μg/mL of Nile Red (pink) to visualize lipid droplets and Hoescht (blue) to stain nuclei. 10-μm size bars shown. (B) Oleate- vs BSA-treated iPSCs were stained with Nile Red or LipidTox Red and visualized via fluorescence microscopy. A separate aliquot of cells was left unstained and subjected to SRS microscopy, in which unstained triglycerides are visualized as white areas. 50-μm size bars shown. (C) Representative histogram of Nile Red fluorescence values of BSA- and 100 μM oleate-treated iPSCs. Cells were stained with Nile Red prior to quantitation by flow cytometry. (D) Biological replicate measures of intracellular lipid levels in iPSCs from 3 donors (n = 4). (E) Geometric means of the Nile Red fluorescence values indicative of intracellular lipids in 30 iPSC lines treated with BSA and 100 μM oleate.
undifferentiated state and after differentiation into iPSC-Heps through a 23-day protocol as we previously described. iPSC-Heps were authenticated by expression of hepatocyte markers and secretion of albumin into the culture media (Supplemental Figure 1, A–B). There were no differences in the levels of intracellular lipids in the isogenic iPSCs and iPSC-Heps, either with values expressed as absolute levels or the magnitude of change between oleate vs. BSA treated cells (Supplemental Figure 1, C–E).

Variants in TM6SF2 (rs58542926), PNPLA3 (rs738409), GCKR (rs1260326), and MBOAT7 (rs641738) are associated with NAFLD in multiple independent cohorts, and have published effect sizes for their association with hepatic fat. All 4 genes had detectable expression in undifferentiated iPSCs, unlike lymphoblastoid cell lines, another patient-derived cell line (Supplemental Figure 2). Importantly, iPSCs carrying increasing numbers of RS58542926 and RS738409 NAFLD risk alleles had greater intracellular lipid accumulation with an additive relationship observed \( (P = 1.4e^{-5}) \) (Figure 2, A). The magnitude of this effect was nearly identical between the 2 risk alleles, consistent with their reported effect sizes (Figure 2, B). Moreover, we found a significant positive correlation \( (r^2 = 0.60; P = 4.8e^{-7}) \) between oleate-induced intracellular lipid accumulation and a weighted genetic risk score based on the reported associations of TM6SF2 rs58542926, PNPLA3 rs738409, GCKR rs1260326, and MBOAT7 rs641738 alleles with hepatic fat (Figure 2, C).

Here, we show that patient-derived iPSCs in their undifferentiated state can be used to model genetic factors that influence individual-level variation in fatty acid-induced lipid accumulation, critical in NAFLD pathobiology. Compared with iPSC-Heps or liver organoids, iPSCs are significantly more scalable, enabling their use for genetic discovery. This could support future use of iPSCs for identifying high-risk individuals, testing variation in response to treatment, and informing the development of precision medicine guidelines for NAFLD prevention and management. Our results also raise the possibility of using iPSCs for investigating genetic influences on other diseases characterized by excess lipid storage. Notably, both the TM6SF2 rs5854296 and PNPLA3 rs738409 risk variants are thought to cause lipid accumulation in hepatocytes by impairing intracellular lipid transport and reducing triglyceride secretion in APOB-containing lipoprotein particles, processes that have not been identified in iPSCs. Additional study is needed to assess the mechanisms underlying these relationships and to determine the extent to which NAFLD relevant pathways can be modeled in the iPSC. Lastly, these findings challenge the current paradigm of iPSC use, which assumes that cells must be differentiated to be informative, highlighting the potential utility of undifferentiated patient-derived iPSCs as a cellular model of individual level disease risk.

Supplementary Materials and Methods

Post Induced Pluripotent Stem Cell (iPSC) Donor Demographics

Cell line donors were genotyped on Illumina Infinium OmniExpressExome bead chips. Thirty-five iPSC lines were selected for this study based on their sex, ancestry, and genetic information (Supplementary Table 1). Because most of the nonalcoholic fatty liver disease (NAFLD) genetic studies have been performed in individuals of European ancestry, we used cell lines from donors of European descent so the effect sizes and genetic risk score would be most accurate.

iPSC and iPSC-derived Hepatocyte-like (iPSC-Hep) Cell Culture

iPSCs were cultured in mTESR1 media at 37 °C at 5% CO2. iPSCs were passaged using accutase (Stemcell Technologies, Cat. # 07920) and media supplemented with Y-27632 2HCl inhibitor (Selleckchem, Cat. # S1049). iPSC-Heps were cultured at 37 °C and 5% CO2 in Lonza Hepatocyte Culture Medium (HCM; Cat. # CC-3198). iPSCs were differentiated into hepatoblasts as previously published.1 Expression of hepatocyte-specific markers albumin and hepatic nuclear factor 4 alpha (HNF4A) were confirmed by fluorescence-activated cell sorting at a threshold of >90% dual-positive cells.

Intracellular Lipid Accumulation

iPSCs and iPSC-Heps were grown to 70% to 75% confluency in 6-well plates. Cell lines were challenged with HCM containing 0 to 100 μM oleate conjugated to fatty acid-free (FAF) bovine serum albumin (BSA), and all BSA-containing supplements were removed. A volume of FAF-BSA containing supplements were added by the oleate condition was used as a negative control. After 24 hours, cells were fixed with 10% paraformaldehyde.

Flow Cytometry for Quantification of Intracellular Lipids

Cells were stained with Nile Red (Sigma, Cat. # 72485) diluted to 100 μg/ml in Dulbecco’s phosphate-buffered saline for 30 minutes, and fluorescence was quantified using the BD LSRFortessa. Data was analyzed using FloJo v10.7.1. Oleate-induced increases in cellular lipids were quantified as the fold change of the oleate-treated/BSA-treated cells. Two outliers were identified using the ROUT test. Because they were from the same batch of samples, all 5 samples in the batch were excluded from the analyses, resulting in a sample size of n = 30. Paired Student t tests were used to identify statistically significant differences between BSA- and oleate-treated cells. Linear regression was used to evaluate the correlation between variation in the magnitude of oleate-induced increase in intracellular lipid accumulation and the number of TM6SF2 rs58542926 and/or PNPLA3 rs738409 risk alleles. All statistical analyses were performed using JMP Pro 16.0.0 and GraphPad Prism version 9.1.0.

Calculation of a Weighted NAFLD Genetic Risk Score

A 4 single nucleotide polymorphism (SNP)-weighted genetic risk score (GRS) was calculated for each iPSC line using the following variants: PNPLA3 rs738409, TM6SF2 rs58542926, GCKR rs1260326, and MBOAT7 rs641738 using previously estimated effect sizes for their relationships with hepatic fat.2 The DHS coefficients used were 0.2653 for each rs738409 G allele, 0.2711 for each rs58542926 T allele, 0.0649 for each rs1260326 T allele, and 0.0575 for each rs641738 T allele. The GRS was calculated as the sum of the product of the weights for each SNP and the numbers of each risk allele present.

Fluorescence Microscopy

Cells were stained with Nile Red (100 μg/mL) and Hoescht 33342 (5 μg/mL) for 30 minutes (ThermoFisher, Cat. # H3570). Images were captured on a Keyence BZ-X700 microscope at 100× and 20× magnification using phase contrast and widefield fluorescence microscopy. Fiji was used to quantify both nuclei and lipid droplet counts as well as the integrated intensity of lipid droplets in 100× images.

Stimulated Raman Spectroscopy (SRS) Microscopy

The dual output of a commercial oscillator/optical parametric oscillator (Insight DS+, Spectra-Physics) was used for SRS imaging. The output of the optical parametric oscillator was set to 802 nm corresponding to a wavenumber of ~2850 cm⁻¹ with the fundamental at 1040 nm used as the Stokes field. The fundamental was amplitude modulated at 10.28 MHz using a resonant EOM (EO-AM-R-C2, Thorlabs) and a Glan-laser polarizer (Thorlabs). The 802 and 1040 nm beams were combined on a 1000 nm short-pass dichroic mirror (Thorlabs) and fed into a commercial inverted scanning microscope (Olympus IX83-FV1200). Temporal coincidence of the pulses was controlled using a variable delay stage placed on the 802 nm arm (FLC200, Newport). A 60× water-immersion objective (1.2 NA) was used for imaging (UPLSAPO60XWIR, Olympus), with a 1.4 NA oil-immersion condenser (CSC1003, Thorlabs) used to collect the light sent to the detector. The Stokes beam was blocked using a 1000 nm shortpass filter (Thorlabs), and the 802 nm pump was detected on a photodiode reverse biased at 61.425 V. The output of the photodiode was demodulated by a lock-in amplifier (H2FLI, Zurich Instruments) for image formation. All images were acquired at 512 × 512 pixels per field of view, using a pixel dwell time of 10 μs, and a lock-in time constant of 3 μs. The average power of both the 802 and 1040 nm lines was 10 mW. Intracellular lipid content was measured as the
integrated SRS signal at 2850 cm⁻¹, which primarily corresponds to CH₂ stretching in lipid molecules. To calculate average cellular lipid content, the images were pseudo-flatfield corrected using a Gaussian convolved version of the image as the flatfield (with radius equal to 150 pixels). A thresholded cellular image for each field of view was then produced by first lowpass filtering the image, and then performing an adaptive local histogram equalization (with radius of 15 pixels).

**RNA Sequencing Analysis**

Isolated RNA was prepared into polyA-selected, strand-specific sequencing libraries for 100 bp paired-end sequencing at the Northwest Genomics Center. Gene expression levels in iPSCs were compared with previously generated RNAseq data, including 426 lymphoblastoid cell lines,³,⁴ primary human hepatocytes from 4 donors (Supplementary Table 3), and 10 HepG2 biological replicates. GTEx V8 liver TPM expression levels were downloaded via the GTEx portal for comparison. Sequence transcript counts per million (TPM) were calculated by dividing the number of sequence fragments aligning to the gene by the gene length in kilobases (FPK). The sum of the FPK for each gene across all samples was then divided by one million to create a scaling factor (FPK/million). The FPK for each sample and gene were then divided by the scaling factor for that gene to create the final TPM value. These values were graphed using Graphpad prism 9.1.0 and shown as Log₁₀ TPM.
**Supplementary Figure 1. Authentication of iPSC-Heps and comparison with iPSCs.**

(A) Brightfield and fluorescence microscopy of iPSCs during differentiation into iPSC-Heps with immunohistochemical evaluation of endoderm (SOX17, FOX2A), and hepatocyte markers (HNFα, alpha fetal protein [AFP], albumin [ALB]) during various stages of differentiation. (B) Albumin in the culture media of iPSCs during differentiation into iHeps and compared with the human hepatoma cell line HepG2. Oncostatin M day 1 to day 5 represent the stage of hepatoblast formation and differentiation into iPSC-Heps at day 6 after addition of oncostatin M (or day 23 after initiating the differentiation protocol). Values shown are mean ± standard error of the mean. (C) Oleate-induced intracellular lipids were imaged at 20× magnification in undifferentiated iPSCs and iPSC-Heps as described in Figure 1. 50-μm size bars shown. (D) iPSC-Heps were treated with BSA or 100 μM oleate (n = 8), and Nile Red fluorescence was quantified by fluorescence-activated cell sorting. **P = .0018, paired t test. (E) Intracellular lipid accumulation was quantified in iPSCs from 8 unique donors before and after differentiation into iPSC-Heps, and after treatment with 100 μM oleate or bovine serum albumin control.
Supplementary Figure 2. Undifferentiated iPSCs express genes identified by NAFLD genetic association analyses. PolyA-selected whole transcriptome sequencing was performed in GTEx liver (n = 226), primary human hepatocytes (n = 4), human iPSCs (n = 48), the human hepatoma HepG2 cell line (n = 10), and human lymphoblastoid cell lines (n = 426), and TM6SF2, PNPLA3, GCKR, and MBOAT7 transcript levels were quantified as transcripts per million. The y-axis is scaled as Log10.

Primary hepatocytes were obtained from 3 female and 1 male donor between the ages of 49 and 75 years with body mass index ranging from 22.5 to 24.3 kg/m².

Note: Informed consent was obtained from all study subjects for the creation of induced pluripotent stem cells, and studies were performed with institutional review board approval of both Kaiser Permanente Northern California and the University of California San Francisco Benioff Children’s Hospitals. Donor individuals were genotyped using Illumina Infinium OmniExpressExome bead chips. A 4 SNP-weighted GRS was calculated for each iPSC line using the following variants: PNPLA3 rs738409, TM6SF2 rs58542926, GCKR rs1260326, and MBOAT7 rs641738. F, Female; GRS, genetic risk score; iPSCs, induced pluripotent stem cells; M, male; SNP, single nucleotide polymorphism.
