ABSTRACT

We study the long-term time-averaged kinetic luminosity, $Q$, of the major flares of the Galactic microquasar GRS 1915+105 and the relationship to the intrinsic X-ray (bolometric) luminosity, $L_{\text{bol}}$, and scale it to that of a complete sample of SDSS/FIRST Fanaroff–Riley (FR) II quasars. If the scale invariance hypothesis for black holes (BHs) holds then we show that the expected distribution in the $Q$–$L_{\text{bol}}$ scatter plane of GRS 1915+105 is consistent with FR II quasars for distances $D = 10.7$–$11$ kpc. We compare the specific values of kinetic luminosity and $L_{\text{bol}}$ during flares of GRS 1915+105 to that predicted by several three-dimensional MHD simulations of BH accretion flows with relativistic ejections. If FR II quasars are a scaled up version of GRS 1915+105, the data are consistent with numerical models when they contain an ergospheric disk jet and the BH spin is $a/M = 0.99$ or $a/M = 0.998$ (we estimate $a/M > 0.984$). In the framework of scale invariance of BHs, our results may imply that FR II quasars also hold rapidly rotating BHs.

1. INTRODUCTION

The black hole (BH) candidate GRS 1915+105 is well known for launching superluminal radio flares out to large distances at a much larger rate than any other Galactic object (Mirabel & Rodriguez 1994; Fender et al. 1999; Dhawan et al. 2000). The X-ray luminosity of GRS 1915+105 is one of the highest of any known Galactic BH candidate (Done et al. 2004). The existence of both relativistic outflows and high continuum luminosity make it tempting to speculate that GRS 1915+105 might be a scaled down version of a radio loud quasar. This is of particular importance because the timescales for radio evolution are reduced from the active galactic nuclei (AGNs) timescales by many orders of magnitude. Thus, unlike quasars, it is in principle possible to see the details of the connection between the putative accretion flow (X-ray luminosity) and the superluminal jet launching mechanism.

In this paper, the idea of GRS 1915+105 as a scaled down Fanaroff–Riley (FR) II quasar is explored. The long-term time-averaged power of the relativistic major flares in GRS 1915+105, $\bar{Q}$, and the luminosity associated with viscous dissipation in the accretion flow, $L_{\text{bol}}$, are re-scaled in order to compare and contrast with the distribution of $\bar{Q}$ and $L_{\text{bol}}$ of a complete sample of FR II quasars. These efforts are rendered credible by the recent study of the power required to launch individual major flares and their accretion state (intrinsic X-ray luminosity or bolometric luminosity, $L_{\text{bol}}$) just hours and minutes before ejection and during the brief 1–7 hr ejection event (Punsly & Rodriguez 2013, PR13 hereafter). The relevant results from PR13 that are required to perform this re-scaling are indicated in Section 2. In Section 3, this is compared to FR II quasars. In Section 4, the results of Sections 2 and 3 are considered in the context of numerical simulations of three-dimensional magnetohydrodynamic (MHD) accretion around spinning BHs.

2. ESTIMATING THE ENERGY OUTPUT FROM RELATIVISTIC EJECTA IN GRS 1915+105

It was determined in Punsly (2012, P12 hereafter), that knowledge of the time evolution of the spectral shape associated with a changing synchrotron self-absorbed opacity, $\tau$, greatly enhances the accuracy of plasmoid energy estimates (constrains the size). The frequency and the width of the spectral peak provide two added pieces of information at each epoch of observation beyond the single epoch spectral index and flux density of the optically thin high-frequency tail that is traditionally used to estimate the ejected plasmoid energy. The evolving $\tau$ combined with baryon number conservation, energy conservation, synchrotron cooling times, and X-ray luminosity were used in P12 to eliminate uncertainty in the energy estimates. Namely, the proton content is minimal and a near minimum energy condition, $E_{\text{min}} \approx m_e c^2$, is shown to occur when the optically thin flux at 2.3 GHz, $S_{\text{thin}}(2.3)$, is near maximum and $\tau \approx 0.1$. In PR13, we assume that the detailed modeling of the time evolution of the flares from P12 can be used as a template for the time evolution of other plasmoids with less supporting data. This determines a set of equations for each flare in PR13 that are solved numerically with four inputs, the peak $S_{\text{thin}}(2.3)$, the spectral index of the optically thin emission, $\alpha$, and the Doppler factor, $\delta$. Figure 1 is a plot of the plasmoid energy estimated in Table 2 of PR13 as a function of the estimated peak $S_{\text{thin}}(2.3)$ for the major flares that were listed in Table 1 of PR13. Except when noted, a fiducial distance to GRS 1915+105 of $D = 11$ kpc is assumed throughout the manuscript. Unlike Table 2 of PR13, the energy is measured in the observer’s reference frame instead of the plasmoid reference frame. The power-law fit in Figure 1 was made with the method of weighted least squares with errors in both variables (Reed 1989). The corresponding power-law fit for each $D$ value is used here to estimate flare energy from a single input, the peak $S_{\text{thin}}(2.3)$. The approximately daily 2.3 GHz and 8.3 GHz
Ejected Energy versus Peak Optically Thin Flux (D = 11 kpc)

\[ E = 4.95 \times 10^{38} \left( \frac{S_{\text{thin}(2.3)}}{1 \text{ mJy}} \right)^{1.408} \text{ ergs} \]

Figure 1. Scatter plot of the estimated energy of superluminal ejections from PR13 evaluated in the observer reference frame vs. the estimated peak \( S_{\text{thin}(2.3)} \).

monitoring with the Green Bank Interferometer provides a database from 1996 to 2000 of 1967 days (taking account of gaps in coverage) for which one can determine \( S_{\text{thin}(2.3)} \). The resulting distributions of major flare energy and number from 1996 to 2000 are plotted in Figure 2.

There are three major sources of uncertainty in the long-term cumulative energy, \( E \), from the flares:

1. The uncertainty in the estimate of the plasmoid energy.
2. The minimal \( S_{\text{thin}(2.3)} \) that is indicative of a superluminal ejection.
3. Possible short (weak) flares missed in the intraday gaps in coverage.

The stochastic error in the first item is ignored because there are sufficient flares to drive the propagated random error to approximately 0. We consider every plausible value of \( D \) and the corresponding dependent \( \delta \) because of the large systematic uncertainty in \( \delta \). In order to estimate \( \delta \) from \( D \), we assume that the kinematic results from Fender et al. (1999) are common to the entire time frame from 1997 to 2000 as evidenced by interferometric observations of multiple flares (Dhawan et al. 2000; Miller-Jones et al. 2005). The intrinsic flux density is \( S_{\text{thin}(2.3)} \delta^{-(3+\alpha)} \). As \( D \) is varied from 10.5 kpc to near the maximum kinematically allowed value of 11 kpc, the intrinsic spectral luminosity changes by a factor \( \approx (0.31/0.54)^{3.9} = (1/8.7) \) which equates to a reduction of the plasmoid energy by a factor of 5–6. Alternatively, the discussions to follow can be phrased in terms of \( \delta \) instead of \( D \). For item 2, we assume that the weakest flares have a peak \( S_{\text{thin}(2.3)} = 30 \text{ mJy} \) since this is the smallest value that can be clearly discerned from a background consisting of core flux variations and previous fading flares. Extrapolating the distributions in Figure 2 to lower cutoffs shows that the total energy output is rather insensitive to the low energy cutoff of the flares—most of the flares are weak, but they carry a small fraction of the total energy output. We estimate the contribution from weak flares in the intraday gaps and the uncertainty from points 2 and 3 to compute \( \bar{Q} \),

\[
\bar{Q} = \frac{\text{cumulative energy of major ejections}}{1967 \text{ days}} = \frac{1.78 \pm 0.21 \times 10^{45} \text{ erg}}{1967 \text{ days}} = 1.04 \pm 0.13 \times 10^{37} \text{ erg s}^{-1}.
\]

3. SCALING TO A SUPERMASSIVE BLACK HOLE

In this section, GRS 1915+105 is re-scaled to FR II quasar values of \( L_{\text{bol}} \). A complete sample of quasars was created in Punsly & Zhang (2011) using the combined Sloan Digital Sky Survey (SDSS) and Faint Images of the Radio Sky at Twenty cm (FIRST) databases. The radio sensitivity was adequate to detect extended emission below the FR I/FR II divide. Thus, a complete distribution of FR II quasars is attained. Furthermore, the \( \bar{Q} \) estimates are far more accurate than other treatments of FIRST data in the literature. Radio images were used to subtract the jet emission and core emission on scales less than 20 kpc in order to more accurately determine the optically thin lobe flux density which is the most robust estimator for \( \bar{Q} \) (Wollott et al. 1999). The blue dots in Figure 3 are the \( \bar{Q} - L_{\text{bol}} \) scatter plot from the top left frame of Figure 3 in Punsly & Zhang (2011) with the conversion from the integrated optical/UV continuum luminosity to \( L_{\text{bol}} \) given by Equation (3) of that paper. The \( L_{\text{bol}} \) estimate is based on flux that is emitted \( \sim 10^{6} - 10^{7} \) yr after the
Figure 2. Distributions of number and energy ejected in major flares emitted from GRS 1915+105 from 1996 to the end of 2000 (see the text for details). The black (red) curve is the cumulative distribution of flare number (energy) in the 1967 days.

Punsly & Rodriguez

The preponderance of plasma that is responsible for $Q$ was ejected from the central engine, based on lobe separation and estimates of lobe advance speeds (Wilott et al. 1999). Thus, the epochs are so displaced in time that there need not be a causal connection. In order to compare GRS 1915+105 to the AGN data, one needs to compare $Q$ in GRS 1915+105 to $L_{\text{bol}}$ at epochs that are not likely to be causally related, i.e., randomly selected from the historical distribution of $L_{\text{bol}}$.

This random data sampling is explored with Monte Carlo simulations. First, we create a distribution of quasar $L_{\text{bol}}$ from the SDSS/FIRST data scatter, $f_{\text{quasar}}(L_{\text{bol}})$. Second, the $L_{\text{bol}}$ distribution of GRS 1915+105 from PR13 Figure 16 and $Q$ from Equation (1) are combined to create a random distribution of $Q/L_{\text{bol}}$, $f_{\text{GRS1915}}[\log(Q/L_{\text{bol}})]$. Then we create pairs of points representing the re-scaled GRS 1915+105 based on re-scaling $L_{\text{bol}}$ to the quasar level. This is accomplished by randomly generating $L_{\text{bol}}$ from $f_{\text{quasar}}(L_{\text{bol}})$ then creating $Q$ randomly for each $L_{\text{bol}}$ from $f_{\text{GRS1915}}[\log(Q/L_{\text{bol}})]$. The red dots in Figure 3 represent Monte Carlo simulations of the re-scaled GRS 1915+105 with $L_{\text{bol}}$ distributed similarly to the SDSS/FIRST FR II sample. The explicit expressions for the quasar luminosity distribution (the blue dots in Figure 3), $f_{\text{quasar}}(L_{\text{bol}})$, are consistent with a log-normal distribution, $Z$, with a mean logarithm (in units of erg s$^{-1}$) of 45.96 and a standard deviation, $0.29$,

$$f_{\text{quasar}}[\log(L_{\text{bol}})] = Z(\mu = 45.96, \sigma = 0.29).$$

The distribution of $L_{\text{bol}}$ for GRS 1915+105 is well described by a log-normal distribution in Figure 16 of PR13,

$$f_{\text{GRS1915}}[\log(L_{\text{bol}})] = Z(\mu = 38.73, \sigma = 0.15), \quad D = 11 \text{kpc}.$$  

From Equations (1) and (3), $\log(Q) = -1.71 + \mu[f_{\text{GRS1915}}[\log(L_{\text{bol}})]]$, thus

$$f_{\text{GRS1915}} \left[ \log \left( \frac{Q}{L_{\text{bol}}} \right) \right] = Z(\mu = -1.71, \sigma = 0.15),$$

$$D = 11 \text{kpc}.$$  

Similar expressions for $D < 11$ kpc follow from Table 2 and the methods of PR13 (see also Figure 2).

For $D = 11$ kpc, the two-dimensional distribution of the re-scaled GRS 1915+105 is cluttered near the peak of the quasar distribution. The smaller dispersion of the simulated data is expected because all points are generated by the same central engine as opposed to a variety of central BH masses and enveloping environments that are responsible for the quasar generated scatter. At $D = 10.7$ kpc, $\lesssim 1/2$ of the simulated data is consistent with FR II quasars and at $D = 10.6$ kpc the distributions have become very distinct. Systematic uncertainty is found by comparing the high biased quasar $Q$ estimates in Figure 3 from Wilott et al. (1999) with the low biased $Q$ estimates from the methods of Punsly (2005) that are based on different assumptions. This yields a systematic uncertainty in $\log Q$ of $0.38 \pm 0.08$, too small to affect the implications of the Monte Carlo simulations. There is very little systematic error in $L_{\text{bol}}$ since it is derived from the integrated continuum near the peak of the spectral energy distribution. The systematic uncertainty in $Q$ for GRS 1915+105 was discussed in Section 2. The main systematic error in $L_{\text{bol}}$ is in the column density, $N_{\text{H}},$ to the source. From Belloni et al. (1997) and Muno et al. (1999), we expect a systematic error less than a factor of two arising from the uncertainty in $N_{\text{H}},$ too small to affect our conclusions.

4. RESULTS IN THE CONTEXT OF SIMULATIONS OF BLACK HOLE ACCRETION

We explore the main results from PR13 in the context of numerical simulations.

1. Strong flares are launched when $L_{\text{bol}}$ is at an elevated level (sometimes approaching the Eddington limit).

2. During the 1–7 hr of major flare ejections, the time-averaged power, $\langle Q \rangle$, and time-averaged intrinsic radiative luminosity, $\langle L_{\text{bol}} \rangle$, are highly correlated.

Our estimates of $L_{\text{bol}}$ are based on models where the main contribution is due to thermal Comptonization of soft (cold $\sim 0.2$ keV) photons by hot ($\sim 20–100$ keV) electrons present in a so-called corona. The important parameters to estimate $L_{\text{bol}}$ are $kT_{\text{inj}}, kT_e, \tau,$ and the Comptonized normalization (see Section 4.2.2 of PR13). $\langle Q \rangle/\langle L_{\text{bol}} \rangle$ for each $D$ is computed from the values in Tables 2 and 3 of PR13 for each flare. The solid line in Figure 4 is $(Q)/\langle L_{\text{bol}} \rangle$ averaged over all the flares for each $D$. The dashed lines represent the standard deviation, $\pm \sigma$. The small dispersion argues strongly for an approximately constant ratio $\langle Q \rangle/\langle L_{\text{bol}} \rangle$ at each $D$. We assume that this is the case and the errors in the individual $\langle Q \rangle$ and $\langle L_{\text{bol}} \rangle$ are artifacts of imperfect data and our estimation methods. Equivalently, the uncertainty in $\langle Q \rangle/\langle L_{\text{bol}} \rangle$ for each $D$ is $\sigma$.

There are two topologically distinct families of three-dimensional MHD simulations of accreting gas near rotating BHs that produce relativistic outflows. The limited flux simulations (LFS hereafter) evolve from the accretion of weak dipolar loops of magnetic flux from the same orientation from a finite torus of gas in the initial state (McKinney & Blandford 2009; Beckwith et al. 2008b; Hawley & Krolik 2006; Krolik et al. 2005). In these simulations, only the leading edge of the poloidal field accretes, so all the accreting large-scale magnetic flux is of one sign. In the LFS, it is the accretion rate not the initial poloidal field strength that regulates the long-term, large-scale magnetic field strength near the BH (and therefore the jet power) through ram pressure in the inner disk (J. McKinney 2011, private communication; A. Tchekhovskoy 2011, private communication in Martínez-Sansigre & Rawlings 2011). Physically, this situation might be considered a brief event of like sign large-scale flux that accretes to the BH and is maintained near the BH by the dynamics of the accretion flow that is driven by a persistent magnetorotational instability (MRI). The physical appeal of LFS is that memory of the initial state is erased and one finds a strong correlation between jet power and accretion rate in accord with the findings of PR13 that were noted above.

The second type of simulation is based on initial conditions that create magnetically choked accretion flows (MCAFs) and magnetically arrested accretion disks (MADs; McKinney et al. 2012; Tchekhovskoy et al. 2011, 2012). A new topology emerges, islands of large-scale magnetic flux perforate the disk, arresting the flow and suppressing the MRI-induced dissipation in these regions. Thus, one would expect the luminosity to be suppressed compared to the LFS. It was shown in PR13 that $\approx 24$ hr before an ejection $L_{\text{bol}}$ is low and jetted emission is minimal, thus it is not an MCAF/MAD state (which have
The Ratio of the Power Required to Eject Plasmoid to the Accretion Flow Luminosity ($\langle Q \rangle / \langle L_{\text{bol}} \rangle$)

Figure 4. ($\langle Q \rangle / \langle L_{\text{bol}} \rangle$) as a function of the assumed distance, $D$, to GRS 1915+105.

maximal jet efficiency). If an MCAF/MAD switches on to drive a major flare, it would imply that the switch-on of an MCAF/MAD jet is preferentially associated with an increase of X-ray luminosity to near the highest historic (non-transient) levels. But this circumstance is contradicted by the implications of our numerical simulations that radiative efficiency should be suppressed in MCAFs/MADs (suppression was also noted in Sikora & Begelman 2013). Since MCAF/MAD simulations do not appear to be representative of the high luminosity during major ejections, in this paper we concentrate on the LFS that can be consistent with the dynamics of GRS1915+105.

In these simulations, the jet power, $Q$, is expressible in terms of accretion rate onto the BH, $\dot{M} c^2$. Thus, one can compare different simulations and one can compare to the observations if the radiative efficiency of the accretion flow due to viscous dissipation $\eta_{\text{th}}$ ($L_{\text{bol}} \equiv \eta_{\text{th}} \dot{M} c^2$) is known. In the numerical models, radiation effects are simulated by ad hoc cooling functions that are based on the local turbulent dissipation driven by MRI. In spite of a physically incomplete methodology for treating the emissivity of the accreting gas, the three-dimensional simulations of accretion disks in Penna et al. (2010), Noble & Krolik (2009), and Noble et al. (2011) have been used to estimate a value,

$$1.0 \eta_{\text{NT}} < \eta_{\text{sim}} \equiv \eta_{\text{th}} < 1.2 \eta_{\text{NT}},$$  \hspace{1cm} (5)

where the range of results are expressed in units of $\eta_{\text{NT}}$, the value from Novikov & Thorne (1973). The disk thickness in these simulations is in the range $0.05 < H/R < 0.2$. We consider this range of $\eta_{\text{sim}}$ from Equation (5) as a reasonable estimate for the $\eta_{\text{th}}$ of the LFS in Figure 5 since they have a compatible range of disk thickness, $0.15 < H/R < 0.2$ (McKinney & Blandford 2009; Hawley & Krolik 2006). Furthermore, it was demonstrated in the simulations of Schnittman et al. (2013) that even if the detailed radiative transfer results in the preponderance of disk luminosity being created by Compton scattering in a disk corona instead of thermal emission from the disk proper, $\eta_{\text{sim}}$ is unchanged to first order and is still consistent with Equation (5). This is an important detail because X-ray spectra during the ejection of major flares do not exist, so the relative contributions of coronal and blackbody components are unknown. The simulations neglect radiation pressure in the disk, so $\eta_{\text{th}}$ in Equation (5) might not be accurate (but see Szuszkiewicz et al. 1996 who calculate <10% change in $\eta_{\text{th}}$ for the relevant Eddington rates).

Figure 5 compares the simulated data to the relationship depicted in Figure 4. The simulated data in the plot were presented and described elsewhere (see Punsly 2011 for details). The only change is that the data are normalized by $L_{\text{bol}} = \eta_{\text{sim}} \dot{M} c^2$ instead of $\dot{M} c^2$. The McKinney & Blandford (2009) $a/M = 0.92$ simulation shows an event horizon jet as in Blandford & Znajek (1977). They note that $Q \approx 0.01 \dot{M} c^2$ is similar to the two-dimensional solutions reported in McKinney (2005). Thus, the spin-dependent $Q$ is given by Equation (3) of McKinney (2005). This normalized jet power is plotted in green in Figure 5. The other event horizon jet data (collectively referred to as Event Horizon Jet (HK) in Figure 5) come from Hawley & Krolik (2006) and Krolik et al. (2005) except for the raw data of Beckwith et al. (2008a) for $a/M = 0.99$ and $a/M = 0.998$ (Punsly 2011). The ergospheric disk jet data are from the simulations, KDE, KDH, and KDJ from Hawley & Krolik (2006) and Krolik et al. (2005). The nature and strength of these jets were described in detail in Punsly et al. (2009) and references therein. In order to remove the artificial variation induced by computational grids covering differing amounts of the ergospheric volume in different simulations, a theoretical fit to the data, “ergospheric disk with normalized inner boundary,” (the red curve) was calculated in Punsly (2011). The fit was shown to exceed the KDE value because the inner boundary of the computational grid is farther from the event horizon in relative units (event horizon radius) than the other simulations. Thus, it does not sample the entire ergosphere (which is critical for high BH spin in Boyer–Lindquist coordinates). The blue band in Figure 5 represents $\langle Q \rangle / \langle L_{\text{bol}} \rangle$ from Figure 4 corresponding to the viable range of $D$ that is compatible with the scaling to FR II quasars in Figure 3, $10.7 \ kpc < D < 11.0 \ kpc$ (the dominant source of uncertainty is $D$). Agreement of the
Jet Power of Major Flares Compared to Limited Flux Simulations

Figure 5. Logarithm of “jet power/\(L_{bol}\)” in the numerical simulations compared to \(\langle Q \rangle/\langle L_{bol} \rangle\) for major flares in GRS 1915+105 based on Figure 4. The limited range of 10.7 kpc < \(D\) < 11 kpc indicated by the blue band is the range of distance for which GRS 1915+105 can be considered a scaled down FR II quasar. The error bars and the range of uncertainty on the curves (the dashed curves) are based on the spread in Equation (5).

(A color version of this figure is available in the online journal.)

simulated data and observations is achieved for an ergospheric disk driven jet with a BH spin, \(a/M = 0.99\) or \(a/M = 0.998\). The theoretical fit in red continuously samples \(a/M\) below 0.99 and indicates agreement for \(a/M > 0.984\). This result agrees with the value of \(a/M = 0.99 \pm 0.01\) that was estimated from the study of X-ray spectra of GRS 1915+105 (McClintock et al. 2006; Blum et al. 2009).

5. CONCLUSION

In this paper, the long-term and episodic behaviors of \(L_{bol}\) and the power of superluminal ejections in GRS 1915+105 were compared and contrasted with FR II quasars under the assumption of scale invariance of BH accretion systems. The results of Section 3 indicate that re-scaling \(L_{bol}\) of GRS 1915+105 to a typical range of \(L_{bol}\) of FR II quasars yields a consistent distribution of \(\Omega\) only if \(D > 10.7\) kpc—otherwise the total energy emitted in the superluminal major ejections is too small. Physically, this constraint on the distance is equivalent kinematically to a Doppler factor \(<0.48\) and a bulk Lorentz factor \(>3.5\) for the approaching plasmoids. Comparison of the GRS 1915+105 data with the results of different three-dimensional numerical simulations of the BH accretion indicate that GRS 1915+105 is compatible with both numerical models and re-scaling to FR II quasars if the numerical models contain an ergospheric disk jet and if \(a/M > 0.984\), in agreement with observational results obtained by different groups and methods. If the analogy with FR II quasars is robust and scale invariance is relevant to astrophysical BHs, the results obtained for GRS 1915+105 may imply that typical radio loud quasars also harbor rapidly spinning BHs.

We thank Igor Igumenshchev for many in-depth discussions on magnetically arrested accretion. We are also grateful to Matt Malkan for sharing his insight into high Eddington rate accretion and the effects on the geometry and efficiency of accretion disk models. JR acknowledges partial funding from the European FP7 grant agreement number ITN 215212 “Black Hole Universe”, and the hospitality of ESO (Garching, Germany) where part of this work was done.
