Abstract

Inspired by the interpretation of two dimensional Yang-Mills theory on a cylinder as a random walk on the gauge group, we point out the existence of a large $N$ transition which is the gauge theory analogue of the cutoff transition in random walks. The transition occurs in the strong coupling region, with the 't Hooft coupling scaling as $\alpha \log N$, at a critical value of $\alpha$ ($\alpha = 4$ on the sphere). The two phases below and above the transition are studied in detail. The effective number of degrees of freedom and the free energy are found to be proportional to $N^{2-\frac{\alpha}{2}}$ below the transition and to vanish altogether above it. The expectation value of a Wilson loop is calculated to the leading order and found to coincide in both phases with the strong coupling value.

Introduction

Yang-Mills theory in two dimensions is at the intersection of many different fields of theoretical physics. It is one example of non trivial completely solvable gauge theory \[1, 2\], in which both perturbative and non perturbative effects can be studied. Its large \( N \) expansion has been proved to describe a two dimensional string theory \[3, 4\], namely a theory of branched coverings on a two dimensional Riemann surface. Non trivial topological sectors in the unitary gauge also seem to be related to matrix string states \[5\]. Its partition function on a torus can be described in terms of a gas of free fermions \[10, 11, 12, 13\], and the kernel on a cylinder by the evolution of a system of \( N \) free fermions on a circle, namely by the Sutherland model.

Some new connections between two dimensional gauge theories and statistical mechanical systems were pointed out in \[6\] where two dimensional gauge theories of the symmetric group \( S_n \) in the large \( n \) limit were investigated. Gauge theories of \( S_n \) also describe \( n \)-coverings of a Riemann surface and hence they are closely related to two dimensional Yang-Mills theories; the relation being essentially provided by Frobenius formula that relates \( U(N) \) characters (in a representation with \( n \) boxes in the Young diagram) to the corresponding characters of the \( S_n \) group.

It was shown in \[6\] that the partition function of a gauge theory on a disc or a cylinder can be interpreted in terms of random walks on the gauge group, whose initial and final positions are the holonomies at the ends of the cylinder\(^2\) and the number of steps is the area of the surface. Although the focus in \[6\] was on the discrete group \( S_n \) the argument can be trivially extended, as it is shown in the Appendix of the present paper, to continuous Lie groups. Similar results were independently obtained in \[16\]. It is well known in random walks theory that after a certain number of steps the end point of the walk becomes independent of the starting point: the walker has lost any memory of the point he started from. The critical number of steps after which that happens can be exactly calculated in a number of situations, and the corresponding transition is known as cutoff transition. Given the correspondence between random walks on the group and gauge theory on a cylinder, one expects to find the cutoff transition also in gauge theories. Indeed it was found in \[6\] that for an \( S_n \) gauge theory where the holonomy on each elementary plaquette is given by a single transposition\(^3\), a cutoff transition occurs in the large \( n \) limit when the number of plaquettes (and hence the area) is \( \frac{1}{2} n \log n \), in agreement with previous results in random walks \[14\]. Models with more general Boltzmann weight for the plaquettes have a richer structure of phase diagrams \[6\]. The stringy interpretation of the cutoff transition in the \( S_n \) gauge theory is the following: beyond the transition the string world sheet is completely connected in the large \( n \) limit, while before the transition the world sheet consists of a large connected part and

\(^2\)In a disc the starting point is the identity of the group, and on a sphere both starting and ending points are the identity.

\(^3\)In terms of the string interpretation this means that in each plaquette there is a single quadratic branch point connecting two of the \( n \) sheets of the world sheet.
of a small fraction (in fact vanishing in the large $n$ limit) of disconnected parts.

Another well known correspondence relates random walks with random graphs [15], that is graphs obtained by randomly connecting $n$ points with $p$ links. These can be put in correspondence with random walks on $S_n$ made of $p$ steps, each step consisting of a simple transposition. Two types of transitions are known in the large $n$ large $p$ double scaling limit in random graphs: a percolation transition at a critical value $\beta = \beta_c$ when $p = \beta n$ and the cutoff transition at $\alpha = 1/2$ when $p = \alpha n \log n$. Beyond the transition, namely for $p > 1/2 n \log n$ all the $n$ points are connected whereas before the transition a vanishing fraction of disconnected points survive.

It is rather natural at this point to look for a similar transition in the large $N$ limit of $U(N)$ gauge theories. A large $N$ phase transition on a sphere and on a cylinder in two dimensional Yang-Mills theories - the Douglas-Kazakov phase transition - has been known for quite some time. However this is not a cutoff transition. In a cutoff transition the partition function on a disc for instance becomes independent on the holonomy on the border of the disc, and this is not the case in the Douglas-Kazakov transition. Besides the Douglas-Kazakov transition occurs at a finite value of the ’t Hooft coupling whereas from the previous examples it appears that the cutoff transition occurs when the area scales as $\log N$ at large $N$. From this point of view the Douglas-Kazakov transition appears more similar to the percolation transition in random graphs, although a precise correspondence is still to be found.

The existence of the cutoff transition in the large $N$ limit of 2D Yang-Mills on the sphere when the ’t Hooft coupling scales as $\log N$ was proved by a simple argument in [6]. The present paper is devoted to study such transition further on both the sphere and the cylinder, in order to characterize its phases and give some physical interpretation. The paper is organized as follows: in Section 1 we review the large $N$ Douglas-Kazakov transition and its physical interpretation. In Section 2 we introduce the cutoff transition on the sphere and study the phases above and below the transition. Section 3 is devoted to the transition on the disc and on the cylinder and Section 4 to the calculation of the expectation value of Wilson loops.

1 Large $N$ transition

The partition function of a pure gauge theory on an arbitrary orientable two-dimensional manifold $\mathcal{M}$ of genus $G$, $p$ boundaries and area $\tilde{A}$ has been known for many years [1, 2]:

\[
Z_{\mathcal{M}} = \int [DA^\mu] e^{-\frac{1}{4\pi^2} \int_{\mathcal{M}} d^2x \sqrt{g} \text{Tr}(F_{\mu\nu}F_{\mu\nu})} = \sum_r \chi_r(g_1) \cdots \chi_r(g_p) q^2 - 2G - p e^{-\frac{1}{4\pi} C_2(r)} .
\]
The sum runs over all irreducible representations of the gauge group, $\lambda$ is the gauge coupling, $\chi_r(g_i)$ is the character of the holonomy $g_i$ in the representation $r$ and $C_2(r)$ is the quadratic Casimir operator in the representation $r$. $A$ is related to the actual area of $M$ through $A = \lambda^2 N \hat{A}$.

We consider $G = 0$ manifolds with at most 2 boundaries; i.e. spheres, discs and cylinders. Moreover, we will confine our analysis to the unitary groups $U(N)$ and $SU(N)$. A third order phase transition in the large $N$ limit was discovered in the case of a sphere by Douglas and Kazakov [7] at a critical value $A = \pi^2$ of the rescaled area $A$. This transition appears to separate a weak coupling ($A < \pi^2$) from a strong coupling ($A > \pi^2$) regime. These results were generalized to the case of a cylinder in [8, 9] where the phase transition was also interpreted as a result of instanton condensation.

The partition function on the sphere can be written as a sum over the set of integers $n_1 > n_2 > \cdots > n_N$ that label the irreducible representations of $SU(N)$ and $U(N)^4$:

$$Z = e^{-\frac{A}{2N^2}(N^2-1)} \sum_{n_1>n_2>\cdots>n_N} \prod_{i<j} (n_i - n_j)^2 \ e^{-\frac{A}{N} \sum_{i=1}^N (n_i)^2}, \quad (2)$$

The existence of a phase transition at the critical value $A = \pi^2$ can be easily derived from (2) by noticing that the partition function (2) is exactly the same as the one of a gaussian hermitian matrix model but with the integral over the eigenvalues replaced by the discrete sum over the integers $n_i$. The solution of a gaussian hermitian matrix model in the large $N$ limit is given by Wigner’s semicircle distribution law for the eigenvalues:

$$|\rho(\lambda)| = \frac{A}{2\pi} \sqrt{\frac{4}{A} - \lambda^2}. \quad (3)$$

where the continuum variables

$$x = \frac{i}{N}, \quad \lambda(x) = \frac{n_i}{N}.$$ 

and the corresponding density of eigenvalues

$$\rho(\lambda) = \frac{\partial x}{\partial \lambda}. \quad (4)$$

have been introduced. In (2) however the would-be eigenvalues $n_i$ are distinct integers and as a consequence the corresponding density $\rho(\lambda)$ in the large $N$ limit is constrained by:

$$|\rho(\lambda)| \leq 1 \quad \forall \lambda. \quad (5)$$

Hence the Wigner semicircle solution is acceptable only in the weak coupling phase, namely for $A \leq \pi^2$ where the condition (5) is fulfilled. In fact the maximum of $|\rho(\lambda)|$

---

4In the case of $U(N)$ the extra condition $n_N \geq -\frac{N-1}{2}$ must be imposed.
occurs at $\lambda = 0$, it increases with the area $A$ and becomes equal to 1 at $A = \pi^2$, as easily seen from (3). The solution in the strong coupling phase $A > \pi^2$ was found in [7] and is expressed in terms of elliptic integrals. In this phase a finite fraction of the eigenvalues condenses, namely the distribution $\rho(\lambda)$ is flat and equal to one in a symmetric interval around $\lambda = 0$ as shown in fig. 2.

![Figure 1: Eigenvalue distribution for $A \leq \pi^2$](image1.png)

![Figure 2: Eigenvalue distribution for $A > \pi^2$ (i.e. DK transition)](image2.png)

1.1 Configuration space

It is well known [10, 11, 12, 13] that the partition function of two dimensional Yang-Mills theories with gauge group $U(N)$ can be interpreted in terms of a gas of $N$ free fermions on a circle described by a Sutherland-Calogero model. In particular, if we denote by $K_2(\theta, \phi; A)$ the kernel on a cylinder of scaled area $A$ and with the $U(N)$ holonomies at the two ends given by the invariant angles $\theta_i$ and $\phi_i$, it was shown that $K_2(\theta, \phi; A)$ can be interpreted as the propagator in a time $A$ from an initial configuration where the positions of the $N$ fermions on the circle are given by $\theta_i$ and a final configuration with positions labeled by $\phi_i$. The partition function on the sphere of area $A$ is a particular case where the initial and final configurations are just $\theta_i = \phi_i = 0$ for all $i$’s, namely the amplitude for a process where all fermions start at the origin and come back to the origin after a time $A$. By a modular transformation on the kernel of the cylinder one finds that the integers $n_i$ labeling the irreducible representations of $U(N)$ are just the discrete momenta of the fermions on the circle. While in the momentum representation the Douglas-Kazakov phase transition can be interpreted as fermion condensation, in the configuration representation it can be seen in terms of instantons condensation [8, 9]. In fact, while going from the initial $\theta_i = 0$ configuration to the final $\phi_i = 0$ configuration, a fermion can in principle wind an arbitrary number of times around the circle. These winding (instantons) configurations do not contribute in the large $N$ limit to the weak coupling phase, as shown by the following simple argument. Consider the Wigner distribution (3) of momenta in the weak coupling phase. The maximum allowed momentum is $n_{\text{max}} = \frac{2}{\sqrt{A}}$, hence the maximum shift in position
for a single fermion in the time $A$ is given by

$$\Delta \theta_{\text{max}} = A \frac{2}{\sqrt{A}} = 2\sqrt{A}$$

(6)

The existence of winding trajectories requires this shift in position to be at least $2\pi$, namely $A$ to be greater of $\pi^2$. Hence the critical value of $A$, where the Douglas-Kazakov phase transition occurs, marks the point where instantons condense, and contribute to the functional integral in the large $N$ limit.

A more detailed understanding of the Douglas-Kazakov phase transition can be achieved by introducing in the large $N$ limit the density $\rho(\theta, t)$ of fermions in the position $\theta$ at a given time (=area) $t$. Due to the compact nature of the configuration space $\rho(\theta, t)$ is defined in the interval $-\pi \leq \theta \leq \pi$ with $\rho(-\pi, t) = \rho(\pi, t)$. Matytsin proved [17] that if the evolution equation of the fermions is given by the Calogero-Sutherland model then the density $\rho(\theta, t)$ is governed by the Das-Jevicki equation [18] which admits Wigner semicircular distribution of radius $r(t)$ as a solution:

$$\rho(\theta, t) = \frac{2}{\pi r(t)^2} \sqrt{r(t)^2 - \theta^2}, \quad |\theta| \leq r(t)$$

(7)

with $r(t)$ satisfying the differential equation $\frac{d^2 r(t)}{dt^2} + \frac{4}{r(t)^3} = 0$. On a sphere of area $A$ the boundary conditions are $r(0) = r(A) = 0$ and the differential equation has the solution:

$$r(t) = 2\sqrt{\frac{t(A-t)}{A}}$$

(8)

The solution given by (7) and (8) is valid provided the support of the density function $\rho(\theta, t)$ is in the interval $[-\pi, \pi]$ at all $t$, namely provided $r(t) \leq \pi$. The maximum value for the radius $r(t)$ occurs for $t = A/2$ and is $r_{\text{max}} = \sqrt{A}$. Hence the condition for the validity of the Wigner semicircular solution is $A \leq \pi^2$. Beyond the critical value $A = \pi^2$ the fermions "realize" that the space they live in is compact, instantons effects become important and (7) is not an acceptable solution any longer. On the cylinder a similar phase transition occurs in general, at a critical value of the area that depends on the holonomies at the boundaries\(^5\). If the distribution of the invariant angles of the holonomies at the boundaries is the Wigner semicircular distribution, then the critical area can be calculated exactly in the same way as for the sphere [8]. For a more general discussion see [9].

\section{Large $A(N)$ phase transition}

It is apparent from the discussion in the previous section and from the explicit form (2) of the partition function that as the area of the sphere increases the distribution

\(^5\)However with particular conditions at the boundary the phase transition may also be absent, see for instance [21].
of the "momenta" $n_i$ (i.e. of the integers that label the $U(N)$ representations) becomes more and more similar to a double step function, like the one drawn with dashed lines in fig. 3. In fact for very large areas the attractive quadratic potential tends to dominate over the repulsive force produced by the Vandermonde determinant. The double step distribution corresponds to the trivial representation of $U(N)$ in which all characters are identical irrespective of their argument. If this distribution dominates the functional integral then the kernel on a disc or on a cylinder becomes independent from the holonomies at the boundaries.

As already mentioned in the introduction and discussed in the Appendix, the partition functions on the disc and on the cylinder may be interpreted in terms of random walks on the group manifold. From this point of view the very large area phase, where the sum over the irreducible representations is dominated by the trivial representation corresponds to a walk which is so long that the walker has lost any notion of the starting point. The transition where this situation sets in is known in random walk theory as "cutoff transition", and the same term will be used here.

The cutoff regime occurs for areas larger than a critical $N$ dependent value $A_c(N)$ which was found in [6]. The argument is very simple: consider the trivial double step representation $R_0$ that minimizes the Casimir term $\sum_i n_i^2$

$$R_0: \{n_1, \ldots, n_N\} = \left\{ \frac{N-1}{2}, \ldots, -\frac{N-1}{2} \right\}.$$  \hfill (9)

and compare its contribution to the partition function (2) with the one coming from a representation $R_1$ in which $n_1$ has been increased by 1, namely in which $n_1 = \frac{N-1}{2} + 1$. In other words we look for the value of $A$ at which $R_0$ ceases to be dominant. A simple calculation shows that the ratio between the two contributions is

$$\frac{Z_0(A, N, R_0)}{Z_0(A, N, R_1)} = e^{\frac{A}{2N^2}}.$$  \hfill (10)

This ratio is larger than 1 (hence $R_0$ dominates and we are in the cutoff phase) if $A > 4 \log N$.

In order to study this phase transition in more detail, it is convenient to parametrize the area $A$ by rescaling it with $\log N$:

$$A = \alpha \log N + \beta$$  \hfill (11)

From the previous argument we expect the cutoff transition to occur at the critical value $\alpha_c = 4$, separating two distinct phases. So Yang Mills theory on a sphere seems to have four phases altogether: the first two at $\alpha = 0$ separated by the Douglas-Kazakov phase transition at $\beta = \pi^2$, the other two when the area is logarithmically rescaled with $N$ that are separated by the cutoff transition.

The aim of this section is to find the saddle point configuration and the free energy in the two phases above and below the cutoff point $\alpha_c = 4$: the cutoff phase
\( \alpha > \alpha_c \) has been discussed above and it is rather trivial, but the phase below \( \alpha_c \) appears as an interesting intermediate phase between the strong coupling phase in the Douglas-Kazakov transition and the cutoff phase. Hence we shall concentrate on this in the rest of the section.

Let us consider again the partition function (2) and the corresponding action

\[
S = 2 \sum_{i>j=1}^{N} \log |n_i - n_j| - \frac{A}{2N} \sum_{i=1}^{N} n_i^2 \tag{12}
\]

We want to find the extremum of this action in the large \( N \) limit, when \( A \) is parametrized as in eq. (11). Since we expect the saddle point distribution of the "momenta" \( n_i \) to be symmetric with respect to the origin (\( n_i \to -n_i \)) we shall perform the variation only with respect to symmetric configurations, that is we set

\[
-M \leq i \leq M, \quad \text{with} \quad M = \frac{N - 1}{2} \quad \text{and} \quad n_{-i} = -n_i, \tag{13}
\]

Using this symmetry one can restrict the sums to non negative values of \( i \) (\( i = 1, \ldots, M \)) and write the action as:

\[
S = 2 \sum_{i>j \geq 1}^{M} \log (n_i - n_j)^2 + \sum_{i>j \geq 1}^{M} \log (n_i + n_j)^2 - \frac{A}{2M} \sum_{i=1}^{M} n_i^2 \tag{14}
\]

While in the cutoff phase \( n_i = i \) for \( i = 1, \ldots, M \) below the cutoff transition we expect a configuration of the type described in fig. 3, namely:

\[
n_i = i \quad i = 1, \ldots, M - l \\
n_{M-l+\alpha} = M - l + \alpha + r_\alpha \quad \alpha = 1, \ldots, l \tag{15}
\]
where the value of $l$ and the spectrum of the integers $r_\alpha$ are to be determined. With these notations the action can be written as:

$$S - S_0 = 4 \sum_{\alpha=1}^{l} \sum_{j=1}^{M-l} \log \left[ \left( 1 + \frac{r_\alpha}{\alpha + j} \right) \left( 1 + \frac{r_\alpha}{M - l + \alpha + j} \right) \right]$$

$$+ \ 2 \sum_{\alpha \neq \beta} \left( \log \left( 1 + \frac{r_\alpha + r_\beta}{\alpha + \beta + 2(M - l)} \right) + \log \left( 1 + \frac{r_\alpha - r_\beta}{\alpha - \beta} \right) \right)$$

$$- \ \frac{A}{2M} \sum_{\alpha=1}^{l} (2(M - l + \alpha)r_\alpha + r_\alpha^2),$$

(16)

where $S_0$ represents the value of the action in the trivial representation $R_0$. We shall assume that as $M \to \infty$ also $l \to \infty$ but at a slower rate than $M$, namely $l/M \to 0$. We shall also assume that $l$ and $r_\alpha$ will be of the same order in the large $M$ limit. These assumptions will be justified a posteriori, in the sense that they will provide a stable saddle point in the large $M$ limit when the area is scaled like $\log M$. They are also very reasonable assumptions: $l$ is of order $N$ in the strong coupling phase following the Douglas-Kazakov transition and one expects that with the logarithmic rescaling of the area it will shrink further by some power of $N$.

The first step in dealing with (16) is to make the dependence from $M$ explicit. By using the identity

$$\prod_{j=1}^{M-l} \left( 1 + \frac{r_\alpha}{j + \alpha} \right) \left( 1 + \frac{r_\alpha}{M - l + j + \alpha} \right) = \frac{(2M - 2l + \alpha + r_\alpha)!}{(2M - 2l + \alpha)!} \frac{\alpha!}{(\alpha + r_\alpha)!}$$

(17)

we can rewrite the action as

$$S - S_0 = 4 \sum_{\alpha=1}^{l} \log \left( \frac{(2M - 2l + \alpha + r_\alpha)!}{(2M - 2l + \alpha)!} \frac{\alpha!}{(\alpha + r_\alpha)!} \right)$$

$$+ \ 2 \sum_{\alpha \neq \beta} \left( \log \left( 1 + \frac{r_\alpha + r_\beta}{\alpha + \beta + 2(M - l)} \right) + \log \left( 1 + \frac{r_\alpha - r_\beta}{\alpha - \beta} \right) \right)$$

$$- \ \frac{A}{2M} \sum_{\alpha=1}^{l} (2(M - l + \alpha)r_\alpha + r_\alpha^2),$$

(18)

All ratios of factorials in (18) can be reduced to the form $\log \frac{(N + C)!}{N!}$ with $N \to \infty$, $C \to \infty$ and $\frac{C}{N} \to 0$. By repeated use of Stirling formula one finds, up to terms that vanish as $\frac{C}{N} \to 0$:

$$\log \frac{(N + C)!}{N!} \sim C \left[ \log N + f \left( \frac{C}{N} \right) \right]$$

(19)
where
\[
f(\frac{C}{N}) = \log(1 + \frac{C}{N}) + \frac{\log(1 + \frac{C}{N})}{C} - 1 = \sum_{k=1}^{M-l} (-1)^{k-1} \frac{z^k}{k(k+1)}.
\] (20)

By using this asymptotic behaviour, and introducing continuum variables in the large \(N\) limit, namely
\[
x = \frac{\alpha}{l}, \quad r(x) = \frac{r_{\alpha}}{l} \sum_{\alpha} = l \int dx.
\] (21)

the action finally takes the form
\[
S - S_0 = 4l^2 \int_0^1 dx [r(x)(\log\left(\frac{M}{l}\right) - \log(x + r(x)) + 1 + \log 2) + x(\log x
\]
\[
- \log(x + r(x)))] + 2l^2 \int_0^1 dx \int_0^1 dy \log(1 + \frac{r(x) - r(y)}{x - y})
\]
\[
- Al^2 \int_0^1 dx r(x)
\] (22)

where subleading terms (by powers of \(\frac{l}{M}\)) have been neglected.

Let us now parametrize the area \(A\) according to eq. (11) and write the action as:
\[
S - S_0 = 4l^2 [F_0 \log M - F_1 \log l + F_2]
\] (23)

where \(F_0\), \(F_1\) and \(F_2\) are of order 1 in the large \(M\) and \(l\) limit and are given by:
\[
F_0 = (1 - \frac{\alpha}{4}) \int_0^1 dx r(x)
\]
\[
F_1 = \int_0^1 dx r(x)
\]
\[
F_2 = \int_0^1 dx \left[ r(x)(-\log(x + r(x)) + 1 - \log 2 - \frac{\beta}{4}) + x(\log x - \log(x + r(x))) \right]
\]
\[
+ \frac{1}{2} \int_0^1 dx \int_0^1 dy \log(1 + \frac{r(x) - r(y)}{x - y})
\]

In order to find the configuration that maximizes the functional integral in the large \(M\) limit we take the variation of (23) with respect to both \(l\) and \(r(x)\). The variation with respect to \(l\) gives the equation:
\[
(1 - \frac{\alpha}{4}) \log M + (\frac{F_2}{F_1} - \frac{1}{2}) = \log l
\] (24)
which shows that $l$ grows like $M^{1-\frac{\alpha}{4}}$. This is consistent with what we expected: for $\alpha \to 0$ it gives $l \sim M$ as in the strong phase beyond the Douglas-Kazakov transition, and at the cutoff point $\alpha = 4$ the power vanishes as expected.

The variation with respect to $r(x)$ gives on the other hand

$$\int_0^1 dy \frac{1}{x + r(x) - y - r(y)} - \log (x + r(x)) = C$$

(25)

with

$$C = \log l - (1 - \frac{\alpha}{4}) \log M + \frac{\beta}{4} + \log 2 = \frac{F_2}{F_1} - \frac{1}{2} + \frac{\beta}{4} + \log 2$$

(26)

If one introduces the new variable $\xi = x + r(x)$ and the density function $\rho(\xi) = \frac{dx}{d\xi}$ with support in the interval $[0, a]$ equation (25) becomes\(^6\):

$$\int_0^a d\eta \frac{\rho(\eta)}{\xi - \eta} - \log \xi = C .$$

(27)

This is a standard type of equation for the density of eigenvalues in the large $N$ limit of matrix models and can be solved by standard analytic methods (for a detailed discussion of this equation see for instance [22]). The resolvent function, whose discontinuity across the cut gives the density $\rho(\xi)$, is given by:

$$H(\xi) = \log \xi + C - 2 \log \left( \frac{\sqrt{\xi - a} + \sqrt{\xi}}{\sqrt{a}} \right)$$

(28)

with the additional condition that for large $\xi$

$$H(\xi) = \frac{1}{\xi} + \mathcal{O}\left(\frac{1}{\xi^2}\right)$$

(29)

The corresponding density is given by

$$\rho(\xi) = \frac{2}{\pi} \arccos \left( \sqrt{\frac{\xi}{a}} \right).$$

(30)

This solution obviously describes, through the symmetry (13), both the positive and the negative region of $n_i$.

The asymptotic condition (29) gives the two extra equations

$$a = 2 ,$$

$$C = \log 2 .$$

(31)

\(^6\)The lowest extreme of the interval is $r(0)$ which is zero by construction, the upper end $a$ is, according with the definition of $\xi$, $a = 1 + r(1)$.
Eq. (30), together with the first of (31) define $r(x)$ completely, although in an implicit way. Hence all integrals involved in the definition of $F_1$ and $F_2$ can be calculated. The calculation can actually be done analytically and gives:

$$F_1 = \frac{1}{4}, \quad \frac{F_2}{F_1} = \frac{1}{2} - \frac{\beta}{4}$$  \hspace{1cm} (32)$$

The second equation could have been derived independently from (26) and (31), so it constitutes a non trivial consistency check. We can now write explicitly $l$ and the free energy $F$ in terms of the area $A(M)$:

$$l = e^{-\frac{\beta}{4}}M^{1-\frac{\alpha}{2}} = Me^{-\frac{A(M)}{4}}$$

$$F = S - S_0 = \frac{1}{2}l^2 = \frac{1}{2}e^{-\frac{\beta}{4}}M^{2-\frac{\alpha}{2}} = \frac{1}{2}M^2e^{-\frac{A(M)}{2}}$$  \hspace{1cm} (33)$$

Beyond the cutoff transition we have instead $F = l = 0$, as the dominant eigenvalue distribution is given by the double step function sketched in fig. 3.

The interpretation of these results from the point of view of the free fermion description is very clear: beyond the cutoff ($\alpha > 4$) we are effectively in a zero temperature situation where all fermions fill the Fermi sea with no holes. Below the cutoff instead ($\alpha < 4$) some excited fermions and the corresponding holes are present in proximity of the surface of the Fermi sea both on the positive and negative momentum side. The number of fermions above the sea level is given by $l$ in (33). The ratio $\frac{l}{M}$ vanishes like $M^{-\frac{\alpha}{2}}$ in the large $M$ limit. This distinguishes this phase from the strong coupling phase of the Douglas-Kazakov transition, where such ratio remains finite, namely the number of fermions above the Fermi sea level is of order $M$.

In spite of being described in terms of $N$ free fermions, the free energy is proportional (with the standard 't Hooft scaling) to $N^2$, which reflects the original number of degrees of freedom in a unitary $N \times N$ matrix model\textsuperscript{7}. So it is not surprising that the free energy becomes proportional to $l^2$ in presence of $l$ effective fermionic degrees of freedom when the area is rescaled by a log $M$ factor. It is as if the effective size of the original matrix had shrunk to $l \times l$. A full understanding of the reduction of number of degrees of freedom from the point of view of the original gauge degrees of freedom is still wanted, although some light on it might be thrown by the study of the kernels on the disc and the cylinder in the following sections.

It is apparent from (33) that the number of effective degrees of freedom $M^{2-\frac{\alpha}{2}}$ is the actual order parameter for the cutoff transition. Incidentally, this unusual dependence of the number of degrees of freedom upon $\alpha$, together with the choice

\textsuperscript{7}The description in the terms of $N$ fermions follows the integration over the angular variables that reduces the matrix model to an integral over the eigenvalues. The ensuing Vandermonde determinant makes the wave function describing the eigenvalues antisymmetric. As a consequence the total momentum of $M$ left moving fermions is of order $M^2$ rather than $M$, that is of the same order as the original number of bosonic degrees of freedom.
of a large $M$ limit, makes it rather delicate to classify such a transition according to standard terminology.

Let us finally consider the representations of $U(N)$ and/or $SU(N)$ that correspond to the "momentum" distribution pictured in fig. 3 and given in (30). With the group $SU(N)^8$ this corresponds to a composite representation in the sense of ref. [4], whose Young diagram is shown in fig. 4 where the constituent representations are denoted by $R$ and $S$. The rows in the Young diagram of $R$ and $S$ (that coincide in this case) have lengths $r_\alpha$ and their total number of boxes $|r|$ is given in the large $N$ limit by

$$\sum r_\alpha \sim l^2 \int dx r(x) = \frac{1}{4} l^2$$

(34)

If the group is $U(N)$ an arbitrary number of columns of length $N$ can be added or subtracted to the Young diagram of fig. 4, and the composite representation can be seen as the direct product of the two constituent representations $R$ and $S$ with opposite $U(1)$ charges. In fact the integers labeling the representation $S$ are in this case negative, which corresponds to changing signs of the invariant angles $\theta_i$, namely to changing $U$ into $U^\dagger$. In the strong coupling regime of the Douglas-Kazakov transition ($A > \pi^2$) the partition function is dominated in the large $N$ limit by a composite representation of the same type but with the Young diagram of $R$ and $S$ made of rows and columns of lengths of order $N$, rather than $l$, and a total number of boxes of order $N^2$ rather than $l^2$.

3 Cutoff transition on the disc and on the cylinder

In this section we are going to consider the partition function on a disc and on a cylinder, with fixed holonomies at the boundaries, in the regime where the area $A$ is scaled as in (11). We shall show that the cutoff transition occurs also in this case at the same critical value of $\alpha$, except for some particular holonomies at the boundaries. This is in analogy to what happens in the case of the Douglas-Kazakov transition which was proved to occur on a cylinder in [8, 9], except possibly for some special configurations (see [21])

We shall use the standard expression for the partition function on a cylinder with holonomies $U$ and $V$ at the boundaries, which is a particular case of (1):

$$Z_{cyl}(U, V) = e^{-\frac{A}{4}(N^2-1)} \sum_r \chi_r(U) \chi_r(V) e^{-\frac{1}{4} \sum_i n_i^2}.$$  

(35)

The partition function on a disc is obtained from (35) by taking for instance $U \rightarrow 1$ and the partition function on the sphere is recovered by taking the double limit

---

8With $SU(N)$ the term $\sum_i n_i^2$ in the action should be replaced by $\sum_i n_i^2 - \frac{1}{4} (\sum_i n_i)^2$ which is invariant under $n_i \rightarrow n_i + a$. However with suitable choice of $a$ the extra term can be set equal to zero.
$U \to 1$ and $V \to 1$. The area $A$ in (35) scales as in (11). The sum over the representations $r$ is replaced in the large $N$ limit by the saddle point, namely by a representation whose "momentum" distribution is of the type described in fig. 3. This corresponds to a composite representation, whose constituent representations $R$ and $S$ have rows and columns of order $l$ with $l/N \to 0$ in the large $N$ limit. The first step in evaluating (35) is then to calculate the characters in such limit.

3.1 Characters in the large $N$, large $l$ limit

For simplicity, let us consider first the case where only one constituent representation is present, which would be the case if only right (or left) moving fermions were present above the Fermi sea. This is given by:

$$n_i = i \quad \text{for} \quad i = 1, \ldots, N-1$$
$$n_i = N - l + \alpha + r_\alpha \quad \text{for} \quad i = N - l + \alpha \quad \text{and} \quad \alpha = 1, \ldots, l \quad (36)$$

The dimension $\Delta_r$ of this representation can be written in the form

$$\Delta_r = \prod_{i>j} \frac{|(n_i - n_j)|}{(i-j)} = \prod_\alpha \frac{\alpha!}{(\alpha + r_\alpha)!} \prod_{\alpha > \beta} \left(1 + \frac{r_\alpha - r_\beta}{\alpha - \beta}\right) \prod_\alpha \frac{(N - l + \alpha + r_\alpha)!}{(N - l + \alpha)!}$$

$$= \frac{d_r}{|r|!} \prod_\alpha \frac{(N - l + \alpha + r_\alpha)!}{(N - l + \alpha)!} = \frac{d_r}{|r|!} N^{\sum r_\alpha} \left[1 + O\left(\frac{l}{N}\right)\right], \quad (37)$$

where $d_r$ is the dimension of the representation of the symmetric group $S_{|r|}$ associated to the Young diagram $r$ of rows $r_\alpha$. The order of the symmetric group is the
total number of boxes in the Young diagram: $|r| = \sum_\alpha r_\alpha$. The dependence on $N$ in (37) is explicit: the ratio of factorials in (37) is a polynomial in $N$ of degree $|r|$. If $l$, $\alpha$ and $r_\alpha$ are all of order $l$ the coefficient of $N^{|r| - k}$ in this polynomial is of order $l^k$ in the large $N$, large $l$ limit. Hence we can write

$$\Delta_r = \frac{d_r}{|r|!} N^{|r|} \left[ 1 + \sum_{k} c_k \left( \frac{l}{N} \right)^k \right]$$

(38)

where the coefficients $c_k$ are smooth in the large $l$, large $N$ limit. If the limit is taken keeping $l/N$ finite, as in the strong coupling phase of the Douglas-Kazakov transition, all terms at the r.h.s. of (38) are of the same order and cannot be neglected. On the other hand if the double scaling limit is taken with $l/N \to 0$, as in the previous section, then all terms after the 1 are subleading and can be neglected.

The same argument holds if instead of the dimension of the representation we consider a character of $U(N)$. In fact the celebrated Frobenius formula gives:

$$\chi_r(U) = \frac{d_r}{|r|!} \sum_{\sigma \in S_{|r|}} \hat{\chi}_r(\sigma) \frac{d_r}{d_r} \prod_j \left( \frac{\text{Tr} U^{s_j}}{N} \right)$$

(39)

where $\hat{\chi}_r(\sigma)$ is a character of the symmetric group $S_{|r|}$ in the representation labeled by the same Young diagram as $\chi_r(U)$, $s_j$ are the lengths of the cycles in the cycle decomposition of $\sigma$ ($\sum_j s_j = |r|$) and $k_\sigma$ is the number of cycles in $\sigma$. By taking $U \to 1$ and comparing (38) and (39) one finds that the contribution of $\frac{\hat{\chi}_r(\sigma)}{d_r}$ when $\sigma$ consists of $k_\sigma$ cycles is $\sim l^{|r| - k_\sigma}$ in the large $l$ limit. So if we take the double scaling limit where both $l$ and $N$ go to infinity and the ratio $l/N$ goes to zero, all terms in the sum over $\sigma$ in (39) are subleading with respect to the one where $\sigma$ is the identity. We obtain:

$$\chi_r(U) = \frac{d_r}{|r|!} \left( \frac{\text{Tr} U}{N} \right)^{|r|} N^{|r|} [1 + \mathcal{O}(l/N)] = \Delta_r \left( \frac{\text{Tr} U}{N} \right)^{|r|} [1 + \mathcal{O}(l/N)]$$

(40)

Notice again that in the strong coupling phase of the Douglas-Kazakov transition, where in the large $N$ limit $l/N$ is kept constant, all terms in (39) coming from different permutations $\sigma$ are of the same order and cannot be neglected.

### 3.2 Partition function on the cylinder and special boundary conditions

As a result of previous analysis we find that in the composite representations that are dominant in the region $0 < \alpha < 4$ the characters $\chi_r(U)$ depend only from $\text{Tr} U$. Hence the partition function on the cylinder will depend only on the trace of the holonomies on the boundaries. In fact it is apparent from (40) that going from
the sphere \((U=1)\) to the cylinder just amounts to a multiplicative factor \(\left(\frac{\text{Tr}U}{N}\right)^{|r|}\).

In the case of interest however the composite representation contains both chiral and anti-chiral component representations (that is \(R\) and \(S\) of fig. 4) and not just one as in the simplified example discussed above. However in the large \(N\) limit the two component representations are decoupled \([4]\) and the character of the composite representation becomes just the product of the characters of the component representations:

\[
\chi_{\text{composite}}(U) = \chi_r(U)\chi_r(U^\dagger) = \Delta_r^2\left(\frac{\text{Tr}U}{N}\right)^{2|r|} \tag{41}
\]

By replacing (41) into (35) we find

\[
Z_{\text{cyl}}(U, V) = Z_{\text{sphere}}\left(\left|\frac{\text{Tr}U \text{Tr}V}{N}\right|\right)^{|r|} \tag{42}
\]

where of course the value of \(|r|\) is the one determined by the saddle point equations and the equality holds, in the large \(N\) limit, only in the regime where the area \(A\) is scaled as in (11) with \(\alpha \neq 0\). If we set \(u = \left|\frac{\text{Tr}U}{N}\right|\) and \(v = \left|\frac{\text{Tr}V}{N}\right|\) it is almost immediate to see that the multiplicative factor at the r.h.s. of (42) is equivalent to replace in the action (23) the constant term \(\beta\) in the area \(A\) with a \(\hat{\beta}(u, v)\) given by:

\[
\beta \rightarrow \hat{\beta}(u, v) = \beta - \log u^2 - \log v^2 \tag{43}
\]

The partition function on the cylinder is then the same as the partition function on a sphere whose area is obtained from the area of the cylinder by adding the two terms \(\log u^2\) and \(\log v^2\). The latter can be interpreted as the areas of the two discs necessary to go, in the given momentum configuration, from \(U = 1\) (resp. \(V = 1\)) to the holonomy at the boundary with \(\left|\frac{\text{Tr}U}{N}\right| = u\) (resp \(\left|\frac{\text{Tr}V}{N}\right| = v\)). The areas of the two discs are of order 1, so this correction does not affect the position of the cutoff transition that remains on the cylinder at \(\alpha = 4\).

The discussion above relies on the fact that the leading term in Frobenius formula (39) comes from the identical permutation. However this is not always true: if we take the large \(N\) and \(l\) limit keeping \(\text{Tr}U = 0\) \(^9\) then all terms in (39) with \(\sigma\) containing cycles of length 1 would vanish. Assuming that \(\text{Tr}U^2 \neq 0\), the term in Frobenius formula (39) with the highest power on \(N\) would then come from permutations \(\sigma\) all made out of cycles of length 2 and would be of order \(N^{|\sigma|}\) instead of \(N^{|r|}\). Supposing that both the trace of \(U\) and of \(V\) vanish the coefficient of \(\log M\) in the first term of (22) would be halved. Correspondingly the critical value of \(\alpha\) at which the cutoff transition occurs would also be halved and become \(\alpha_c = 2\).

Let us make this argument general and more quantitative. Let us assume that \(\text{Tr}U^{k_1} \neq 0\) with \(\text{Tr}U^{j} = 0\) for \(j < k_1\) and the same for \(V\) with \(k_2\) at the place of \(k_1\).

---

\(^9\)This can happen for instance if the holonomy at a boundary has a symmetry of some sort, for instance of the type \(\theta \rightarrow \theta + \pi\), that is preserved through the limiting process.
The leading term in (39) will now be:

\[ \chi_r(U) = \frac{d_r}{|r|!} \left( \frac{\text{Tr} U^{k_1}}{N} \right)^{|r|/k_1} \hat{\chi}_r(\sigma) N^{|r|/k_1} \]  

(44)

where \( \sigma \) consists of \( \frac{|r|}{k_1} \) cycles of length \( k_1 \)

10 From the discussion following (39) we assume that in the large \( l \) limit \( \frac{\hat{\chi}_r(\sigma)}{d_r} \sim r^{\nu(1-\frac{\alpha}{4})} \) By using this asymptotic behaviour and eq. (44) we can write the partition function on the cylinder in the large \( N \) and \( l \) limit as in (23), but with \( F_0 \) and \( F_1 \) replaced by the following expressions:

\[ F_0 = \left( \frac{1}{2k_1} + \frac{1}{2k_2} - \frac{\alpha}{4} \right) \int_0^1 dx r(x) \]

\[ F_1 = \left( \frac{1}{2k_1} + \frac{1}{2k_2} \right) \int_0^1 dx r(x) \]  

(45)

The dependence of \( F_2 \) from \( r(x) \) is modified, in a so far unknown way, by next to leading terms in \( \frac{\hat{\chi}_r(\sigma)}{d_r} \)

11 while the constant parameter \( \beta \) is replaced by

\[ \beta \rightarrow \tilde{\beta}(u_{k_1}, v_{k_2}) = \beta - \frac{1}{k_1} \log u_{k_1}^2 - \frac{1}{k_2} \log v_{k_2}^2 \]  

(46)

where, with obvious notations, \( u_{k_1} = \frac{|\text{Tr} U^{k_1}|}{N} \) and \( v_{k_2} = \frac{|\text{Tr} V^{k_2}|}{N} \). Although the equation for \( r(x) \) cannot be derived, the variation with respect to \( l \) gives the scaling power of \( l \) and the cutoff transition point:

\[ l \sim M^{1-\frac{\alpha}{4(k_1+\frac{1}{2})}} \]  

(47)

The cutoff transition occurs then at critical point \( \alpha_c(k_1, k_2) \) given by:

\[ \alpha_c(k_1, k_2) = 4 \left( \frac{1}{2k_1} + \frac{1}{2k_2} \right) \]  

(48)

which generalizes the result on the sphere.

4 Wilson loops

In this section we calculate the expectation value of a Wilson loop in a Yang-Mills theory with gauge group \( U(N) \) in the large \( N \) limit. The space-time manifold has the topology of a two dimensional sphere whose area scales like \( \log N \) as in eq. (11).
We shall follow the approach of Daul and Kazakov [23] and Boulatov [24] who did the calculation for constant areas.

We may think of the sphere of area $A$ as two discs of areas $A_1$ and $A_2$ ($A_1 + A_2 = A$) sewed along their common boundary and with holonomy on the boundary respectively $U$ and $U^\dagger$. The Wilson loop is then given by

$$W(A_1, A_2) = \langle \frac{1}{N} \text{Tr} U \rangle$$

$$= \frac{1}{Z} \sum_{R_1, R_2} d_1 d_2 \int dU \frac{1}{N} \text{Tr} U \chi_1(U) \chi_2(U^\dagger) e^{-\frac{A_1}{2N} C_1 - \frac{A_2}{2N} C_2}$$

where $d_1$ and $C_1$ are the dimension and the Casimir operator in the representation $R_1$, referred to the disc of area $A_1$; likewise for $d_2$ and $C_2$. The quantity $\int dU \text{Tr} U \chi_1(U) \chi_2(U^\dagger)$ may be either 0 or 1, namely it is 1 when the Young diagram of $R_2$ is obtained by adding one box to the diagram of $R_1$ and 0 otherwise. That is, if $R_1$ is labeled by the integers $n_1 > n_2 > \cdots > n_N$, $R_2$ is labeled by a set on integers where one of the $n_i$ is increased by one. Daul and Kazakov used this property to get rid of one summation and obtained

$$W(A_1, A_2) = \frac{1}{Z} \sum_{R_1} \frac{1}{N} \sum_i d_i^2 \prod_{j, j \neq i} \left( 1 + \frac{1}{n_j - n_i} \right) e^{-\frac{A_1 + A_2}{2N} C_1} e^{\frac{A_2}{2N} n_i},$$

where the sum over $i$ corresponds to all the possible ways of adding one box to the diagram. This is not however the whole result, in fact the original expression is symmetric under exchange of $A_1$ and $A_2$, so a term with $A_1$ and $A_2$ exchanged must be added to (50) and gives:

$$W(A_1, A_2) = \frac{1}{Z} \sum_{R_1} \frac{1}{N} \sum_i d_i^2 \prod_{j, j \neq i} \left( 1 + \frac{1}{n_j - n_i} \right) e^{-\frac{A_1 + A_2}{2N} C_1} \left( e^{\frac{A_1}{2N} n_i} + e^{\frac{A_2}{2N} n_i} \right).$$

Moreover, eq. (50), as well as (51), is clearly not symmetric under $n_i \leftrightarrow -n_i$, so we can not restrict our considerations to $n_i > 0$ any longer; instead we have to consider the whole interval $-\infty < n_i < \infty$.

Let us first compute $W(A_1, A_2)$ in the frozen phase where the sum over $R_1$ is dominated by the trivial representation of dimension $d_1 = 1$ labeled by $n_i = i - \frac{N + 1}{2}$.  

\footnote{This term originates from the fact that $\int dU \text{Tr} U \chi_1(U) \chi_2(U^\dagger)$ is different from zero also if the representation conjugate to $R_1$ is obtained from the representation conjugate to $R_2$ by adding a box in the Young diagram.}
∀i and $R_2$ is the fundamental representation of dimension $d_2 = N$ with $C_2 - C_1 = N$. By inserting this into (51) one finds:

$$W(A_1, A_2) = (e^{-\frac{A_1}{N}} + e^{-\frac{A_2}{N}})$$

(52)

which is, as expected, a typical strong coupling result. If for instance $A_1 >> A_2$, then we have

$$W(A_1, A_2) \sim e^{-\frac{A_2}{N}}$$

(53)

Since $A = A_1 + A_2 = \alpha \log N + \beta$, this situation can occur in two ways:

1) $A_2 = \beta_2, A_1 = \alpha \log N + \beta_1$: then $W \sim e^{-\frac{\beta_2}{N}}$

2) $A_1 = \alpha_1 \log N + \beta_1, A_2 = \alpha_2 \log N + \beta_2$ with $\alpha_1 > \alpha_2$: then $W \sim N^{-\frac{\alpha_2}{N}}$.

We proceed now to evaluate $W(A_1, A_2)$ in the phase before the cutoff, namely for $\alpha < 4$. The sum over representations in (51) can be replaced by the contribution of the dominant representation in the large $N$ limit, calculated on the sphere in section 2. The saddle point is unaffected by the presence of the extra term

$$\sum_i \prod_{j,j \neq i} \left(1 + \frac{1}{n_j - n_i}\right) \left(e^{\frac{A_1}{N}n_i} + e^{\frac{A_2}{N}n_i}\right)$$

which is subleading with respect to the action. After replacing in (51) the sum with the saddle point contribution, some simplifications occur and we get

$$W(A_1, A_2) = \frac{1}{N} \sum_i \prod_{j,j \neq i} \left(1 + \frac{1}{n_j - n_i}\right) \left(e^{\frac{A_1}{N}n_i} + e^{\frac{A_2}{N}n_i}\right).$$

(54)

The representation in (54) is of the type given in (15), and the sum over $i$ describes all possible ways of adding a box to the Young diagram. However the replacement $n_i \rightarrow n_i + 1$ is impossible in the region $-l \leq i \leq l$ as the resulting sequence of integers would not be monotonic increasing. So the sum over $i$ in (54) can be replaced by a sum over $\alpha$ with $1 \leq \alpha \leq l$. As a matter of fact we must consider only positive $\alpha$'s, as adding a box to the adjoint representation amounts to symmetrize with respect to $A_1$ and $A_2$, and it has been taken already into account. Hence in (54) we must replace the index $i$ with $\alpha$, $n_i$ with $M - l + \alpha + r_\alpha$ while the index $j$ goes from $-M$ to $M$, namely it goes over both the condensed and the non condensed regions. With these substitutions the expression for the Wilson loop becomes:

$$W(A_1, A_2) = \sum_{\alpha=1}^{l} \xi_\alpha \left[1 - \frac{1}{N} \left(1 - \frac{\xi_\alpha}{l}\right)\right]$$

$$e^{\sum_{\beta=1}^{l} \log \left(1 + \frac{1}{\xi_\alpha - \xi_\beta}\right)} \left(1 - \frac{1}{N}\right)^{\gamma_\alpha} + \{A_2 \rightarrow A_1\}$$

(55)

where

$$\xi_\alpha = \alpha + r_\alpha$$

(56)
It is convenient as usual to use in the large $N$ limit the continuum variables $x = \alpha l$, $\xi(x) = \xi_\alpha l$ and the density function $\rho(\xi) = \frac{d\xi}{d\eta}$. The crucial part of the calculation is the evaluation of $\sum_{\beta=1}^l \log \left(1 + \frac{1}{\xi_\alpha - \xi_\beta}\right)$ which can be done following ref. [23]. By expanding the logarithm one finds:

$$\sum_{\beta=1}^l \log \left(1 + \frac{1}{\xi_\alpha - \xi_\beta}\right) = \int d\eta \rho(\eta) \frac{1}{\xi - \eta} - \sum_{k=2}^l \frac{1}{k} \sum_{\beta} \frac{1}{(\beta - \alpha)^k} \rho(\xi)^k$$  \hspace{1cm} (57)

The first term at the r.h.s. comes from the $k = 1$ term of the log expansion and can be evaluated using eq. (27), the other terms can be calculated as in [23] and give $\log \frac{\sin \pi \rho}{\pi \rho}$. By inserting these results into (55) and using the explicit form of the solution (30) one finally obtains (neglecting $O(\frac{1}{N})$ terms):

$$W(A_1, A_2) = 2 \int d\xi \frac{\sin \pi \rho}{\pi} \left(e^{-\frac{A_1}{2}} + e^{-\frac{A_2}{2}}\right) = e^{-\frac{A_1}{2}} + e^{-\frac{A_2}{2}}$$  \hspace{1cm} (58)

which is exactly the same result as in the frozen phase. The result is not trivial, but it was somehow to be expected. Both phases, before and after the transition, are strong coupling phases and the expectation value of the Wilson loop should be in both of them obtained, to the leading order, by filling the loop with elementary plaquettes in the fundamental representation. The effects of the transition are expected to appear only at the next-to-leading order ($\sim \frac{1}{N}$) which is sensitive to the $O(\frac{1}{N})$ degrees of freedom which are not frozen below the cutoff.

S.A. would like to thank the Niels Bohr Institute for warm hospitality during the early stage of this work.

**A  Gauge theories as random walks**

The equivalence between random walks on a group $G$ and two dimensional gauge theories with gauge group $G$ was pointed out in [6]. This equivalence states that the partition function of a gauge theory on a disc of area $A$ and holonomy $g$ on the boundary coincides with the probability that a suitably defined random walk on the group leads, in a number of steps proportional to $A$, from the identity in the group to the group element $g$. A similar relation holds for the partition function on the cylinder. In ref. [6] the attention was focused on discrete groups, where the number of steps can be directly identified with the area measured in suitable units, and
in particular on the symmetric group $S_n$. In this appendix we extend, in a rather straightforward way, the argument presented there to the case of gauge theories on continuous Lie groups. Similar conclusions have in the meantime appeared in the literature [16].

Let us consider a random walk on $G$ with the transition probability defined as follows: if the walker is in $g_p \in G$ after $p$ steps, then his position after $p + 1$ steps is obtained by left multiplying $g_p$ by an element $g$, chosen in $G$ with a probability $t(g)$. We assume $t(g)$ to be a class function, whose character expansion can then be written as:

$$t(g) = \sum_r \Delta_r \chi_r(g) t_r .$$

(59)

where $\Delta_r$ is the dimension of the representation $r$. Suppose that the random walk starts from an element $g_0 \in G$ and denote by $K_p(g, g_0)$ the probability for the walker to be in $g$ after $p$ steps. Of course $K_0(g, g_0)$ is a delta function, namely:

$$K_0(g, g_0) = \sum_r \Delta_r \chi_r(g_0^{-1} g_0)$$

(60)

Given $K_p(g', g_0)$, the probability for the walker to be in $g$ after $p + 1$ steps is given by:

$$K_{p+1}(g, g_0) = \int dg' t(g(g')^{-1}) K_p(g', g_0) ,$$

(61)

where $dg'$ is the Haar measure. By using (59), (60) and (61) it is easy to show by induction that $K_p(g', g_0)$ is a class function of $gg_0^{-1}$. In fact let us assume that this is true for $K_p(g', g_0)$, namely that $K_p(g', g_0)$ admits the character expansion

$$K_p(g', g_0) = \sum_r \Delta_r k_r^{(p)} \chi_r(g' g_0^{-1})$$

(62)

Then by replacing (62) and (59) into (61) and performing the integration over $g'$ using the characters fusion rules, one finds that $K_{p+1}(g, g_0)$ admits a similar expansion with

$$k_r^{(p+1)} = t_r k_r^{(p)}$$

(63)

As a result $K_p(g, g_0)$ is given by:

$$K_p(g, g_0) = \sum_r \Delta_r \chi_r(g g_0^{-1}) \tilde{t}_r^p$$

(64)

Since we are dealing with a random walk on a continuous Lie group, we expect the walk to be a smooth path. This is obtained by letting the number of steps $p$ go to infinity and at the same time the length of each step to zero. Each step corresponds then to a very small move on the group manifold, that is $t(g)$ is close
to a delta function $\delta(g)$, namely according to (59), $\tilde{t}_r \simeq 1$. We implement this by choosing

$$\tilde{t}_r = e^{-\varepsilon h(r)}, \quad \text{with} \quad \varepsilon \to 0$$

(65)

If we set $g_0 = 1$ in (64),

$$\lim_{\varepsilon \to 0} \lim_{p \to \infty} p \varepsilon = A \quad \text{and} \quad h(r) = \frac{C_2(r)}{2N}$$

(66)

we reproduce exactly the partition function of a gauge theory on a disc of area $A$, thus establishing the desired connection. A random walk with an arbitrary transition function $h(r)$ will be related to a generalized Yang-Mills theory with the corresponding potential [19, 20].

The partition function on a cylinder may be associated to the probability of a random walk from a generic point $g_0$ (in general different from the identity) to $g$. However in order to obtain the correct answer we need to consider a random walk not on the group manifold itself, but rather in the space of orbits, where all group elements belonging to the same equivalent class are identified. This amounts to replacing in (64) $g_0 \to h^{-1} g_0 h$ and integrating over $h$. This produces a new transition probability $\tilde{K}_p(g, g_0)$ which is separately a class function of both $g$ and $g_0$ and is given by:

$$\tilde{K}_p(g, g_0) = \sum_r \chi_r(g) \chi_r(g^{-1}_0) \tilde{t}_r^p$$

(67)

This coincides with the kernel on the cylinder, with the parameters identified according to (66).
