Low FVC/TLC in Preserved Ratio Impaired Spirometry (PRISm) is associated with features of and progression to obstructive lung disease

Spyridon Fortis¹,², Alejandro Comellas², Victor Kim³, Richard Casaburi⁴, John E. Hokanson⁵, James D. Crapo⁶, Edwin K. Silverman⁷ & Emily S. Wan⁷,⁸

One quarter of individuals with Preserved Ratio Impaired Spirometry (PRISm) will develop airflow obstruction, but there are no established methods to identify these individuals. We examined the utility of FVC/TLC in identifying features of obstructive lung disease. The ratio of post-bronchodilator FVC and TLC from chest CT (FVC/TLC_Ct) among current and former smokers with PRISm (FEV₁/FVC ≥ 0.7 and FEV₁ < 80%) in COPDGene was used to stratify subjects into quartiles: very high, high, low, and very low. We examined the associations between FVC/TLC_Ct quartiles and (1) baseline characteristics, (2) respiratory exacerbations, (3) progression to COPD at 5 years, and (4) all-cause mortality. Among participants with PRISm at baseline (n = 1,131), the very low FVC/TLC_Ct quartile was associated with increased gas trapping and emphysema, and higher rates of progression to COPD at 5 years (36% versus 17%; p < 0.001) relative to the very high quartile. The very low FVC/TLC_Ct quartile was associated with increased total (IRR = 1.65; 95% CI [1.07–2.54]) and severe (IRR = 2.24; 95% CI [1.29–3.89]) respiratory exacerbations. Mortality was lower in the very high FVC/TLC_Ct quartile relative to the other quartiles combined. Reduced FVC/TLC_Ct ratio in PRISm is associated with increased symptoms, radiographic emphysema and gas trapping, exacerbations, and progression to COPD.

Among individuals in the general population with at least 10 pack-years of cigarette smoking who undergo spirometry, 12% have a post-bronchodilator FEV₁% predicted below 80% with a FEV₁/FVC ratio ≥ 0.71. This “non-specific” spirometric pattern, commonly referred to as “restrictive”, has been designated as Preserved Ratio Impaired Spirometry (PRISm)2–7. Smokers with PRISm have higher cumulative smoking exposure, reduced exercise capacity, and increased mortality compared to smokers with normal lung function1,2,7. PRISm is also associated with thicker airway walls relative to smokers with normal spirometry2. PRISm individuals share features with COPD patients, and a quarter of subjects with PRISm eventually develop COPD1,2. The range of post-bronchodilator FEV₁% predicted and percent emphysema on CT among PRISm subjects is wide, indicative of a heterogeneous population2. Clustering analysis identified a “PRISm-COPD” subgroup with lower FEV₁/FVC ratio and higher radiologic CT emphysema relative to the rest of PRISm subjects3. This subgroup may represent individuals with early or occult obstructive lung disease who do not meet current diagnostic thresholds for airflow limitation.

In PRISm, total lung capacity (TLC) may help distinguish a restrictive from an obstructive ventilatory defect, according to the American Thoracic Society-European Respiratory Society (ATS-ERS) 2005 guidelines. However, a true "restrictive disease" is very unlikely in individuals with risk factors for obstruction lung disease, no interstitial lung disease and unremarkable body mass index (BMI). In COPDGene, the prevalence of PRISm is 12% despite the fact that participants with interstitial lung disease were excluded and body mass index (BMI) in PRISm individuals was slightly higher than the BMI in smokers with normal lung function. In addition, a single center study showed that among individuals with PRISm and TLC above the lower limit of normal (LLN), only 26% had a clinical diagnosis of obstructive lung disease. Moreover, only 15% of those with PRISm and TLC > LLN develop obstructive spirometry over a median follow-up time of 3 years. Currently, there is no available diagnostic test in clinical practice to identify which patients with PRISm may have features classically associated with obstructive lung disease.

In obstructive lung diseases, residual volume (RV) may increase at the expense of FVC with total lung capacity (TLC) remaining normal. Conversely, RV may increase with a preserved FVC resulting in an increased TLC. Both processes result in reduced FVC/TLC ratio which may antedate the development of obstruction diagnosed using standard FEV1/FVC criteria. A disproportionate decrease of FVC relative to TLC may occur in patients with a restrictive ventilatory defect that coexists with obstructive lung disease. Thus, FVC/TLC represents a composite measure that may be able to identify an occult obstructive ventilatory defect. FVC can be readily obtained from spirometry, while TLC, typically assessed by plethysmography, can also be quantified using an inspiratory chest CT (TLCCT), with prior studies demonstrating strong correlations with the plethysmography results.

We hypothesized that reduced FVC/TLC ratio in PRISm is associated with clinical, functional and radiographic features of obstructive lung disease, acute respiratory events and increased mortality, and progression to COPD. To investigate our hypothesis, we examined current and former smokers with PRISm enrolled in the COPDGene study.

Methods

Data collection. We analyzed data from participants in the COPDGene study, an ongoing study conducted at multiple clinical centers through the United States (http://www.copdgene.org/). Participants were current and former smokers with ≥10 pack-years of smoking who self-identified as non-Hispanic whites (NHW) or African Americans (AA) and were between the ages of 45–80 years at enrollment. The institutional review boards at each participating center approved the study protocol and written informed consent was obtained from all participants. Details of the study protocol have been published previously. Briefly, participants completed a modified American Thoracic Society Respiratory Epidemiology questionnaire, St. George's Respiratory Questionnaire (SGRQ), and 6-minute walk test (6-MWT) at the enrollment visit. Dyspnea was assessed using the modified Medical Research Council (mMRC) scale. Participants performed pre- and post-bronchodilator spirometry. The complete study protocols were performed in accordance with the relevant guidelines and regulations of American Thoracic Society–European Respiratory Society (ATS-ERS). Volumetric chest CT scans were obtained at TLCCT (maximal inspiration) and at functional residual capacity (FRCCT) end-tidal expiration using multidetector CT scanners. FRC and TLC% predicted were calculated based on the predicted values. Percent emphysema and gas trapping were quantified using 3D Slicer software (www.airwayinspector.org).

Definitions and outcomes. PRISm was defined as post-bronchodilator FEV1 < 80% predicted and FEV1/FVC < 0.7. COPD was defined as post-bronchodilator FEV1/FVC < 0.7. The FVC/TLCCT ratio at enrollment was calculated using post-bronchodilator FVC (in liters) from spirometry, while TLCCT was measured from volumetric inspiratory chest CT scans.

Co-morbidities and medication usage were self-reported. Percent emphysema was defined by using the percentage of lung volume at TLCCT with attenuation less than −950 Hounsfield units (HU). Gas trapping was quantified as the percentage of lung volume at FRC with attenuation values less than −856 HU. Parametric response mapping analysis was performed on paired registered inspiratory and expiratory images to distinguish functional small airways disease (PRMAD) from emphysema by Imbio LLC (Minneapolis, MN) using lung density analysis software. As previous described, we defined PRMAD as the percentage of lung with evidence of gas trapping not due to emphysema (i.e. areas of lung with attenuation < −856 HU on expiration minus area of lung with attenuation < −950 HU on inspiration).

Change in FEV1 between enrollment and 5-year follow up visit was calculated using post-bronchodilator spirometry. Severe exacerbations were defined as episodes of worsening respiratory symptoms requiring use of antibiotics and/or systemic steroids. Severe exacerbations were defined as those requiring hospitalizations or emergency room visits. Other variable definitions have been previously described.

Statistical analysis. We stratified PRISm participants at the enrollment visit into quartiles by FVC/TLCCT: very high, high, low, and very low. We compared the characteristics of PRISm individuals at the enrollment visit, rates of progression to COPD at the 5-year follow-up visit, and exacerbations over the time between the FVC/TLCCT quartiles. We used Spearman’s rank correlation to examine changes in continuous variables with
increasing FVC/TLC\textsubscript{CT}. We used the Cochran Armitage trend test to examine proportion changes with increasing FVC/TLC\textsubscript{CT} quartile.

We created multivariable logistic and linear regression models with chronic bronchitis, mMRC and SGRQ scores, radiographic measures and 6-MWT distance at the enrollment visit as the dependent variable (outcome) and post-bronchodilator FVC/TLC\textsubscript{CT} quartile at the enrollment as the independent variable (predictor). All models included the following covariates: age and current smoking status at enrollment, gender, race, pack-years smoked, body mass index (BMI), history of asthma and congestive heart failure. There were no missing values in any of the covariates. We also performed a multivariable linear and logistic regression analysis with change in FEV\textsubscript{1}, 6-MWT distance, radiographic measurements, and progression to COPD at the follow-up visit as the dependent variable (outcome) and post-bronchodilator FVC/TLC\textsubscript{CT} quartile at enrollment as the independent variable (predictor). We included the following covariates in these models: age and current smoking status at enrollment, gender, race, pack-years smoked, body mass index (BMI), history of asthma and congestive heart failure, and change of BMI between enrollment and follow-up visit.

For the exacerbation analysis, we created zero-inflated negative binomial models which included adjustment for age and current smoking status at enrollment, gender, race, pack-years smoked, BMI, chronic bronchitis, history of asthma and congestive heart failure. There were no missing values in any of the covariates. Follow-up time was included as an offset in the models as previously described\textsuperscript{36}.

We used Cox proportional hazard regression models to examine the association between post-bronchodilator FVC/TLC\textsubscript{CT} quartile with all-cause mortality. Models included the following covariates: age, gender, race, smoking status, smoking pack-years, BMI, diabetes, history of asthma and congestive heart failure. There were no missing values in any of the covariates.

In sensitivity analyses, we repeated selected analyses using PRISm defined as post-bronchodilator FEV\textsubscript{1} < LLN with a post-bronchodilator FEV\textsubscript{1}/FVC \geq LLN and COPD defined as post-bronchodilator FEV\textsubscript{1}/FVC < LLN using the NHANES III reference values\textsuperscript{27}. All statistical analyses were conducted using R statistical software (http://www.r-project.org/) using the following R software packages: ‘dunn.test’, ‘FSA’, ‘pscl’, ‘MASS’, ‘AER’, ‘survival’, and ‘DescTools’.

**Ethics approval.** The institutional review boards at each participating center approved the study protocol. Details of the study protocol have been published previously\textsuperscript{38}.

**Results**

Of 10,199 COPDGene participants with at least 10 or more pack-years of smoking and no significant interstitial lung disease or bronchiectasis, 1,260 of them had PRISm at the enrollment visit. After excluding one individual with no available post-bronchodilator spirometry, 121 with no TLC\textsubscript{CT} measures and 7 individuals with FVC > TLC\textsubscript{CT}, 1,131 participants were included in the analysis. The median value of FVC/TLC\textsubscript{CT} was 0.59 (IQR = 0.53–0.66). Of these 1,131 participants, 617 of them had acceptable spirometry measurements at the 5-year follow-up visit, 967 had available data regarding respiratory exacerbations, and 960 had vital status data available.

**Baseline characteristics at the enrollment visit (n = 1,131).** Table 1 shows the characteristics of participants by FVC/TLC\textsubscript{CT} quartile. Age, BMI, pack-years smoking exposure, mMRC and SGRQ scores, % emphysema and gas trapping, and % functional small airways disease increase with decreasing FVC/TLC\textsubscript{CT}. An increased proportion of females and decreased proportion of African Americans were associated with decreasing FVC/TLC\textsubscript{CT}. Participants in the lower FVC/TLC\textsubscript{CT} quartiles a higher prevalence of comorbidities.

In multivariable-adjusted analyses, the very low FVC/TLC\textsubscript{CT} quartile was associated with an average of 3.31% higher radiographic gas trapping (95% CI = 1.85–4.76; p < 0.001), and 3.26% higher PRM\textsubscript{FAD} (95% CI = 1.40–5.12; p < 0.001) relative to the very high quartile (Fig. 1). Lower quartiles were also associated with higher % emphysema. The very low quartile was associated with a trend towards higher SGRQ (3.63; 95% CI = −0.17 to 7.44; p = 0.06) (Supplementary Table S1).

**Progression to COPD at 5-year follow-up.** Among participants with valid spirometry at the 5-year follow-up visit (n = 617), approximately 35.9% (56 of 156) of individuals in very low FVC/TLC\textsubscript{CT} quartile progressed to COPD, while 23% (37 of 160), 22% (35 of 156), and 17% (25 of 145) of individuals in the low, high, and very high FVC/TLC\textsubscript{CT} quartiles, respectively, progressed to COPD (Fig. 2; Cochran-Armitage test for trend p < 0.001). In the multivariable-adjusted analysis, the very low FVC/TLC\textsubscript{CT} quartile at enrollment was associated with progression to COPD with an OR of 2.67 (95% CI = 1.45–5.00; p = 0.001) relative to the highest quartile (Supplementary Table S2).

**Longitudinal changes in spirometry, functional capacity, and radiographic features.** Supplement Table S2 shows changes in spirometry, functional capacity, and radiographic features between enrollment and follow-up visit. In the adjusted analysis, the very low FVC/TLC\textsubscript{CT} quartile at enrollment was associated with increase of 2.74% radiographic gas trapping (95% CI = 0.55–4.93; p = 0.014) relative to the highest quartile (Supplementary Table S3). FVC/TLC\textsubscript{CT} was not associated with change in FEV\textsubscript{1}, 6-MWT distance or % emphysema over time. There were no differences in the rate of decline in FEV\textsubscript{1} by current smoking status at enrollment (combined and by FVC/TLC\textsubscript{CT} quartile - data not shown).

**Respiratory exacerbations.** Of 967 subjects with exacerbation data available, 349 (36.1%) reported at least one exacerbation and 196 (20.3%) reported at least one severe exacerbation during a median follow-up time of 6.4 years (IQR = 3.8 to 7.4). Approximately, 44% (115 of 262), 37% (93 of 250), 31% (72 of 232), and 31% (69 of 223) in the very low, low, high, and very high Quartiles had at least one exacerbation during the time period (Cochran-Armitage trend test p < 0.001). In the very low, low, high, and very high Quartiles, 26% (67 of 262),
glucocorticosteroids, LABA
Mortality (n = 248) subjects died in the Very Low quartile, 11% (27 of 246) died in the low quartile, 11.3% (28 of 247) died in the very high quartile relative to all other quartiles (high, low, very low) combined, a reduced risk of mortality was observed in the very high quartile (Table 2). In a Cox proportional hazards model examining individuals in the very high quartile relative to all other quartiles (high, low, very low) combined, a reduced risk of mortality was observed (HR = 0.53, 95% CI = 0.28–0.97, p = 0.040).

Table 1. Baseline characteristics of smokers with preserved ratio impaired spirometry across post-bronchodilator forced vital capacity/total lung capacity ratio (FVC/TLC\textsubscript{C\textsubscript{T}}) quartiles (n = 1,131). 1For % GT and FRC\textsubscript{C\textsubscript{T}}% analysis, data were available for 936 subjects. 2For PRM data analysis, data were available for 932 subjects. 3For 6-MWT data analysis, data were available for 1,121 subjects. BDR = bronchodilator response; BMI = body mass index; CAD = coronary artery disease; CHF = congestive heart failure; DM = diabetes mellitus; FRC\textsubscript{C\textsubscript{T}}% = functional residual capacity % predicted; HTN = hypertension; ICS = inhaled glucocorticosteroids, LABA = long-acting beta-agonist, LAMA = long-acting muscarinic antagonist, mMRC = modified Medical Research Council dyspnea score; OSA = obstructive sleep apnea; post-FEV1% = post-bronchodilator FEV1% predicted; post-FVC% = post-bronchodilator FVC% predicted; PRM\textsuperscript{2D} = parametric response mapping functional small airways disease; SD = standard deviation; SGRQ = St. George's Respiratory Questionnaire score; TLC\textsubscript{C\textsubscript{T}}% = total lung capacity % predicted and 6-MWD = 6-min walk test.

Mortality (n = 960). During a median follow-up time of 2,408 days (IQR = 2,158 to 2,622), 12.9% (32 of 248) subjects died in the Very Low quartile, 11% (27 of 246) died in the low quartile, 11.3% (28 of 247) died in the High quartile, and 5.9% (13 of 219) died in the very high quartile (Cochran-Armitage trend test p = 0.02). A Kaplan-Meier plot of mortality by FVC/TLC\textsubscript{C\textsubscript{T}} quartile at enrollment is shown in Fig. 4. In Cox proportional hazards models adjusted for age at enrollment, sex, race, BMI, current smoking at enrollment, cumulative smoking exposure, diabetes, history of asthma and congestive heart failure, increased mortality in the high quartile with a trends towards an increased mortality in the low and very low quartiles relative to the very high quartile was observed (Table 2). In a Cox proportional hazards model examining individuals in the very high quartile relative to all other quartiles (high, low, very low) combined, a reduced risk of mortality was observed (HR = 0.53, 95% CI = 0.28–0.97, p = 0.040).
Sensitivity analysis. When PRISm was defined using LLN criteria, we observed similar findings with those in main analysis except that FVC/TLCCT was significantly associated with chronic bronchitis, increased mMRC and SGRQ and the association with mortality was attenuated (Supplementary Tables S5–S9 and Fig. S1).

Figure 1. Associations between post-bronchodilator forced vital capacity/total lung capacity (FVC/TLCCT) quartiles at enrollment with dyspnea and health-related quality of life scores, chest CT % emphysema and % gas trapping, functional small airway disease, and 6-min walk test distance at baseline among smokers with Preserved Ratio Impaired Spirometry (PRISm; n = 1,131). Each panel in the figure represents a separate linear regression model with categorical post-bronchodilator FVC/TLCCT quartile as the main independent variable (exposure) with the “very high” quartile used as the reference category. The dependent variable (outcome) in each model was (A) modified Medical Research Council (mMRC) dyspnea score, (B) St. George’s Respiratory Questionnaire total score (SGRQ), (C) 6-minute walk test distance (6-MWT in meters), (D) % Emphysema, (E) % Gas trapping, and (F) functional small airways disease (PRMfSAD). All models were adjusted for the following co-variates: age, sex, race, smoking status, smoking pack-years, body mass index (BMI), history of asthma and congestive heart failure, and diabetes mellitus. FVC/TLCCT quartile is plotted on the x-axis while the regression coefficient (and 95% CI) for each category is plotted on the y-axis.

* For % GT analysis, n = 936 subjects. † For PRMfSAD data analysis, n = 932 subjects. # For 6-min walk test distance analysis, n = 1,121 subjects.

Figure 2. Progression to COPD (FEV1/FVC < 0.7) at the 5-year follow-up visit by post-bronchodilator forced vital capacity/total lung capacity ratio (FVC/TLCCT) quartiles at enrollment in smokers with preserved ratio impaired spirometry (n = 617). Cochran Armitage Trend test p < 0.001. Pairwise comparisons between quartiles performed using Chi-squared test. *p = 0.026 vs Very High FVC/TLCCT Quartile.
Discussion

Our study explores the utility of FVC/TLC ratio in former and current smokers with PRISm as a potential tool to identify individuals with features of and possible increased risk for progression to obstructive lung disease. In our cohort, very low FVC/TLC was associated with radiographic findings traditionally associated with COPD as well as progression to COPD and respiratory exacerbations while very high FVC/TLC was associated with reduced mortality.

PRISm is a common spirometric pattern with a prevalence between 5% and 20%. Although often referred to as a "restrictive spirometric pattern", 30–40% of patients with PRISm do not have reduced TLC. On average, individuals with PRISm have higher BMI, but obesity alone does not decrease vital capacity or TLC below the LLN in most individuals. Notably, only about 5% of patients undergoing bariatric surgery for extreme obesity have PRISm at preoperative assessment.

PRISm is comprised of a heterogeneous population with a wide range of BMI, degree of lung function impairment, and radiographic emphysema likely due to different underlying pathological processes in each individual.
mortality. In this manuscript, we utilize FVC/TLC, which decreases in obstructive lung disease\(^1\), as a conceptual surrogate for RV (which was not directly measured in our cohort) to identify individuals with features obstructive lung disease within PRISm. Our finding that individuals with PRISm with low FVC/TLC have increased radiographic emphysema and gas trapping complements work from the SPIROMICS cohort, where that RV/TLC was shown to be associated with increased radiographic emphysema and gas trapping in smokers with normal lung function\(^39\). Apart from the fact that RV/TLC was not available in our cohort, we used FVC/TLC as it may be more sensitive to identify the presence of small airway disease than RV/TLC because FVC, a dynamic measure obtained at forced expiration, will capture dynamic collapse and air trapping not present during slow exhalation maneuver\(^15,32\). Future studies should examine the role of RV/TLC in PRISm. In addition, we did not examine FRC/TLC as FRC can be reduced remarkably in obesity\(^38\) which may render difficult to interpret those measures when an obstructive lung diseases coexists.

Our findings suggest that low FVC/TLC\(_{CT}\) may be a possible marker of early obstructive pulmonary disease. Nevertheless, participants in the very low FVC/TLC\(_{CT}\) quartile have higher BMI; this contrasts with the common knowledge that patients with established obstructive pulmonary disease have often lower BMI. Previous studies have shown an inverse relationship of BMI with mortality in COPD, known also as the “obesity paradox” with confounders such as exercise capacity and muscle mass possibly contributing towards favorable outcomes\(^33,34\). In addition, despite the fact that obesity does not typically reduce the FVC below the LLN in subjects without lung disease\(^39\), higher BMI decreases FVC and increases the FEV\(_1)/FVC ratio which can lead to underdiagnosis of obstructive pulmonary disease\(^11,35\). In COPD subjects with established airflow obstruction, increasing BMI is associated with higher FEV\(_1)/FVC\(^35\).

We acknowledge that the fixed threshold FEV\(_1)/FVC < 0.7\) diagnostic criterion for COPD endorsed by Global Initiative for Chronic Obstructive Lung Disease(GOLD) may have also misclassified individuals with obstructive lung disease as PRISm. In a recent large population-based sample (n = 24,207), Bhatt and colleagues showed that the discriminative accuracy of FEV\(_1)/FVC < 0.7\) to predict COPD-related death and/or hospitalization was not inferior to FEV\(_1)/FVC < LLN\(^36\). We assert that because the majority of our findings remained robust on sensitivity analyses using LLN-defined lung function categories. FVC/TLC ratio can be utilized to identify individuals with features of obstructive lung disease regardless of whether fixed-threshold or LLN criteria are used.

In COPDGene, 40.5% of PRISm individuals and 32.5% of smokers with normal lung function are African American\(^1\). Differences in the reliability of prediction equations may lead to the “overdiagnosis” of African American with PRISm in the absence of true pathology; this may contribute to the lower rates of African Americans in the low FVC/TLC\(_{CT}\) quartiles. It is also unclear why females were relatively over-represented in the lower FVC/TLC\(_{CT}\) quartiles. Whether PRISm represents a gender-specific pathway to COPD, or whether traditional FEV\(_1)/FVC criteria systematically misclassify women with COPD is not known\(^37,38\). Our sensitivity analysis using gender and race specific spirometric criteria to define PRISm showed similar findings. Future studies, especially in cohorts of diverse ancestry and ethnicity, are warranted to further explore these findings.

Previous studies have shown that air trapping is associated with FEV\(_1)\) decline. In current and former smokers with at least 20 pack-years smoking and normal lung function, RV/TLC is associated with FEV\(_1)\) decline\(^30\). We have extended these findings by showing that air trapping (low FVC/TLC) in individuals with PRISm is associated with progression to COPD. General population studies have also shown that individuals with abnormal non-obstructed lung function are at risk for developing COPD\(^39,40\). It may seem counterintuitive that low FVC/TLC\(_{CT}\) in PRISm was associated with progression to COPD and respiratory exacerbations, but was not associated with FEV\(_1)\) decline, increase in emphysema, and change in 6-MWT distance over time\(^41\). Within COPDGene, individuals with PRISm are at increased risk for respiratory exacerbations relative to smokers with normal lung function\(^35\). However, respiratory exacerbations in PRISm do not result in significant excess lung function decline in FEV\(_1)\) as observed in individuals with established airflow limitation\(^41\). A survivor bias may also be present in FEV\(_1) decline analysis\(^41\). Participants that had poor lung function and low FVC/TLC may have died before the follow-up visit. Similarly, we may have not observed changes in 6-MWT distance likely due to the high variability of the test\(^44,45\).

Population-based studies have shown that PRISm is associated with increased cardiac\(^7\) and all-cause mortality\(^12,22\). While the increased average BMI in PRISm as a whole may mediate some of the risk associated with increased mortality, the association between very high FVC/TLC\(_{CT}\) and lower mortality relative to all other quartiles despite concurrent adjustment for BMI, congestive heart failure, and diabetes status in our study suggests

| Quartile   | FVC/TLC\(_{CT}\) | HR   | 2.5%  | 9.75%  | P value |
|------------|-----------------|------|-------|--------|---------|
| Very High  | ref             | ref  | ref   | ref    | ref     |
| High       | 2.12            | 1.09 | 4.13  | 0.028  |         |
| Low        | 1.68            | 0.84 | 3.36  | 0.14   |         |
| Very Low   | 1.87            | 0.89 | 3.87  | 0.10   |         |

Table 2. Associations of post-bronchodilator forced vital capacity/total lung capacity (FVC/TLC\(_{CT}\)) quartiles at enrollment with mortality in smokers with Preserved Ratio Impaired Spirometry (PRISm; n = 960). Cox Hazard regression models with post-bronchodilator FVC/TLC\(_{CT}\) quartiles as independent variables (exposure) and mortality as the dependent variable(outcome) were performed. All models for mortality included the following co-variates: age, sex, race, smoking status, smoking pack-years, body mass index (BMI), history of asthma and congestive heart failure, and diabetes mellitus. HR = Hazard Ratio.
our composite measure may have utility in the risk-stratification of individuals with PRISm. Previous studies in
COPD have shown associations between RV and mortality\(^ {46}\). In Veterans with a history of smoking and normal
lung function, Zeng \textit{et al}. showed that RV/TLC is associated with increased respiratory medication use, hospital-
izations, and all-cause mortality\(^ {47}\).

Our study is the first one showing that a composite measure of lung function may help to identify patients with
PRISm who eventually progress to classic airflow obstruction and are at increased risk for respiratory excava-
tions and death. The strengths of our study include large sample size, highly granular epidemiological data, axial
radiographic imaging data, and longitudinal data on clinically relevant outcomes. Despite this, we acknowledge
the following limitations. RV was not available in our cohort. TLC\(_{\text{CT}}\) was measured in supine position by chest
CT, which is usually lower than TLC measured in seated position by plethysmography\(^ {13}\). Another limitation is
possible self-selection bias of subjects who returned for a follow-up visit. Since our cohort includes only smokers,
our findings cannot be generalized to non-smoking populations and future studies in independent cohorts are
warranted. In conclusion, FVC/TLC\(_{\text{CT}}\) can help to identify individuals with PRISm at increased risk for clinical
events and progression to COPD, and who would benefit from smoking cessation and may be a potential target
population for treatment trials in the future.
