Abstract
In this work, we present a numerical study of the wave stability of steady solitary waves over a localised topographic obstacle through the full Euler equations. There are two branches of the solutions: one from the perturbed uniform flow and the other from the perturbed solitary-wave flow. We find that steady waves from the perturbed uniform flow are always stable with respect to perturbations of its amplitude. Regarding the perturbed solitary wave, when the perturbed initial condition has smaller amplitude than the steady solution, we notice a certain type of stability. Yet, when the perturbed initial condition has larger amplitude than the steady solution an onset of wave-breaking seem to occur.

1 Introduction

Water waves is a field of many interesting physical problems. For instance, problems related to the propagation of water waves over topographic obstacles (Baines 1995; Pratt 1984), ship wakes and ocean waves generated by storms (Johnson 2012).

The interaction wave-current-topography has been extensively studied in the past few years using different mathematical models. Perhaps, the forced Korteweg-de Vries equation (fKdV) is the more commonly nonlinear model used. The fKdV equation arises as a model for submerged obstacles with small amplitudes in nearly critical flows, i.e., when the Froude

number defined as

\[ F = \frac{U_0}{\sqrt{gh_0}}, \]  

is close to 1. Here, \( U_0 \) is the uniform flow speed, \( g \) is the gravity and \( h_0 \) is the average depth of the channel. The flow is called supercritical or subcritical depending on whether \( F > 1 \) or \( F < 1 \). A careful study on this model was first done by Wu and Wu (1982) and later by several other authors (Akylas 1984; Grimshaw and Smyth 1986; Wu 1987; Wu and Wu 1982; Milewski 2004; Flamarion et al. 2019; Flamarion and Ribeiro-Jr 2021a; Flamarion 2021).

On the light of the full Euler equations, Vanden-Broeck and Tuck (1985) investigated steady subcritical waves generated by a moving pressure distribution and their connection with ship generated waves. Later, Asavanant et al. (2001) studied the same problem considering both the subcritical and supercritical regimes. They explored different parameter regimes, including effects of pressure intensity and distribution length. Binder et al. (2005) used the boundary integral method to compute steady supercritical solutions in the presence of two triangles along the bottom. More recently, Grimshaw and Maleewong (2013) studied the stability of steady solutions of fKdV equation in both subcritical and supercritical regimes. They found their steady wave from the transient fKdV solution, whose stability was then analyzed through the Euler equations in the presence of a moving pressure distribution. In the presence of a constant current and a topography, Vanden-Broeck (1994) used a boundary integral method to compute steady solutions for the Euler equations. Several types of steady waves were found but their stability was not analyzed. Later, Flamarion et al. (2019) presented an iterative numerical method based on conformal mapping technique to study waves generated by a current-topography interaction for the full Euler equations and compared their results with the ones produced by the fKdV equation. They observed that the two models agreed well in the weakly nonlinear weakly dispersive regime. In addition, a few types of steady waves were computed through a Newton’s method type.

In this work, we compute numerically steady waves for the full Euler equations in the presence of a topographic obstacle and study their wave stability. Although other authors have already study the same problem, the novelty of the present work is the study of the wave stability. We find two branches of solutions: the perturbed uniform flow and the perturbed solitary-wave flow. The steady waves from the perturbed uniform flow are always stable with respect to perturbations of its amplitude. Regarding the perturbed solitary wave, when the perturbed initial condition has smaller amplitude than the steady solution, we find a certain type of stability. However, the steady wave solutions are unstable when the perturbed initial condition has larger amplitude than the steady solution and an onset of a wave-breaking seem to occur at later times. This study is a natural step up from fKdV results reported by Chardard et al. (2011).

This article is organized as follows. In Sect. 2, we present the mathematical formulation of the Euler equations. In Sect. 3, we describe the conformal mapping technique and rewrite the Euler equations in the canonical domain, which is a uniform strip. In Sect. 4, we present a numerical method to solve them. Section 5 contains the numerical results and Sect. 6 the conclusion.

## 2 Mathematical formulation

We consider a two-dimensional incompressible and irrotational flow of an inviscid fluid with constant density \( \rho \) in the presence of gravity \( g \), a uniform upstream current \( U_0 \) in the
presence of a topographic obstacle \( h(x) \) in a channel with typical depth \( h_0 \) in the far field. We denote the velocity potential by \( \phi(x, y, t) \) and the free surface profile by \( \zeta(x, t) \). We choose \( h_0, (gh_0)^{1/2} \) and \( (h_0/g)^{1/2} \) as our reference units in space, speed and time, respectively. Thus, the dimensionless Euler equations are

\[
\begin{align*}
\phi_{xx} + \phi_{yy} &= 0, & \text{for } -1 + h(x) < y < \zeta(x, t), & x \in [-L, L], \\
F h_x + \phi_x h_x &= \phi_y, & \text{at } y = -1 + h(x), & x \in [-L, L], \\
\zeta_t + F \zeta_x + \phi_x \zeta_x - \phi_y &= 0, & \text{at } y = \zeta(x, t), & x \in [-L, L], \\
\phi_t + F \phi_x + \frac{1}{2} (\phi_x^2 + \phi_y^2) + \zeta &= 0, & \text{at } y = \zeta(x, t), & x \in [-L, L],
\end{align*}
\]

where \( F = U_0/(gh_0)^{1/2} \) is the Froude number and \( 2L \) is the physical domain length.

In the next section, we rewrite Eq. (2) using the conformal mapping technique, which allow us to solve them numerically.

3 Conformal mapping

Consider the conformal mapping from the canonical \( w \)-plane (\( w = \xi + i \eta \)) onto the physical \( z \)-plane (\( z = x + iy \)),

\[ z(\xi, \eta, t) = x(\xi, \eta, t) + iy(\xi, \eta, t), \]

satisfying the boundary conditions

\[ y(\xi, 0, t) = Y(\xi, t) \quad \text{and} \quad y(\xi, -D, t) = -1 + H(\xi, t), \]

where \( H(\xi, t) = h(x(\xi, -D, t)) \) and \( Y(\xi, t) = \zeta(x(\xi, 0, t), t) \). It is required that the canonical strip’s height \( D \) is a function of time \( t \). Imposing that the physical and canonical domain to have the same length (\( 2L \)), we find that

\[ D(t) = 1 + \frac{1}{2L} \int_{-L}^{L} Y(\xi, t) - H(\xi, t) d\xi. \]

More details of this conformal mapping are presented by Dyachenko et al. (1996), Flamarion et al. (2019) and Flamarion and Ribeiro-Jr (2021b).

We denote by \( \phi(\xi, \eta, t) = \tilde{\phi}(x(\xi, \eta, t), y(\xi, \eta, t), t) \) and \( \psi(\xi, \eta, t) = \tilde{\psi}(x(\xi, \eta, t), y(\xi, \eta, t), t) \) the potential and its harmonic conjugate in the canonical domain. Let \( \Phi(\xi, t), \Psi(\xi, t), X(\xi, t) \) and be the traces of \( \phi, \psi \) and \( x \), respectively. Substituting the new variables in Kinematic and Bernoulli conditions (2) \(_{3,4}\) a straight-forward computation shows that the Euler equations in
the canonical domain are

\[
\begin{align*}
X_\xi &= 1 - C \left[ Y_\xi - \mathcal{F}^{-1} \left( \frac{\hat{H}_\xi(k_j, t)}{\cosh(k_j D)} \right) \right], \\
\Phi_\xi &= -C \left[ \Psi_\xi(\xi, t) + \mathcal{F}^{-1} \left( \frac{F \hat{H}_\xi(k_j, t)}{\cosh(k_j D)} \right) \right], \\
Y_t &= Y_\xi C \left[ \frac{\Theta_\xi}{J} \right] - X_\xi \frac{\Theta_\xi}{J}, \\
\Phi_t &= -Y - \frac{1}{2J} (\Phi_\xi^2 - \Psi_\xi^2) + \Phi_\xi C \left[ \frac{\Theta_\xi}{J} \right] - \frac{1}{J} F X_\xi \Phi_\xi, \\
X_b(\xi, t) &= x(\xi, -D, t) = \xi - C \left[ \mathcal{F}^{-1} \left( \frac{\hat{Y}(k_j, t)}{\cosh(k_j D)} - \frac{\hat{H}(k_j, t)}{\cosh^2(k_j D)} \right) \right] + T \left[ H(k_j, t) \right],
\end{align*}
\]

where \( \Theta_\xi(\xi, t) = \Psi_\xi + F Y_\xi \), \( J = X_\xi^2 + Y_\xi^2 \) is the Jacobian of the conformal mapping evaluated at \( \eta = 0 \), \( C \) and \( T \) are the operators

\[
\begin{align*}
C &= \mathcal{F}^{-1}_{k_j \neq 0} i \coth(k_j D) \mathcal{F} k_j \neq 0 \quad \text{and} \quad T = \mathcal{F}^{-1}_{k_j \neq 0} i \tanh(k_j D) \mathcal{F} k_j \neq 0,
\end{align*}
\]

where the Fourier modes are given by

\[
\begin{align*}
\mathcal{F}_{k_j} [g(\xi)] &= \hat{g}(k_j) = \frac{1}{2L} \int_{-L}^{L} g(\xi) e^{-ik_j \xi} d\xi, \\
\mathcal{F}^{-1}_{k_j} [\hat{g}(k_j)](\xi) &= g(\xi) = \sum_{j=\infty}^{\infty} \hat{g}(k_j) e^{ik_j \xi},
\end{align*}
\]

with \( k_j = (\pi/L) j, j \in \mathbb{Z} \).

Steady waves are obtained from the set of Eq. (3) imposing \( \partial_t = 0 \). Following Flamarion et al. (2019), we conclude that \( \Theta = 0 \) and

\[
\Psi_\xi(\xi) = -F Y_\xi(\xi).
\]

Therefore, Eq. (3) are now written as

\[
\begin{align*}
X_\xi(\xi) &= 1 - C \left[ Y_\xi - \mathcal{F}^{-1} \left( \frac{\hat{H}_\xi(k_j, t)}{\cosh(k_j D)} \right) \right], \\
\Phi_\xi(\xi) &= -C \left[ \Psi_\xi(k_j) + \mathcal{F}^{-1} \left( \frac{F \hat{H}_\xi(k_j, t)}{\cosh(k_j D)} \right) \right], \\
Y_t &= Y_\xi C \left[ \frac{\Theta_\xi}{J} \right] - X_\xi \frac{\Theta_\xi}{J}, \\
\Phi_t &= -Y - \frac{1}{2J} (\Phi_\xi^2 - \Psi_\xi^2) + \Phi_\xi C \left[ \frac{\Theta_\xi}{J} \right] - \frac{1}{J} F X_\xi \Phi_\xi = 0, \\
X_b(\xi) &= x(\xi, -D, t) = \xi - C \left[ \mathcal{F}^{-1} \left( \frac{\hat{Y}(k_j)}{\cosh(k_j D)} - \frac{\hat{H}(k_j)}{\cosh^2(k_j D)} \right) \right] + T \left[ H(k_j) \right],
\end{align*}
\]

In the next section, we present the numerical methods to compute steady waves and their evolution.
4 Numerical methods

The numerical approaches presented below is the same reported by Flamarion et al. (2019) for rotational flows with constant vorticity and similar to the one proposed by Viotti et al. (2014) for irrotational flows. Here, we only summarise the main steps.

4.1 Steady wave solutions

Numerical steady waves of the Euler equations (4) are found on a domain $\xi \in [-L, L]$, with $N$ uniformly spaced points with grid size $\Delta \xi = 2L/N$. On the grid points $\xi_n$, $n = 1, 2, \ldots, N$, the free surface elevation is denoted by $Y_n = Y(\xi_n)$. The steady Bernoulli equation is written as

$$ G_n(Y_1, Y_2, \ldots, Y_N) := Y(\xi_n) + \frac{1}{2} J(\Phi_{\xi,n}^2 - \Psi_{\xi,n}^2) + \frac{1}{2} F X_{\xi,n} \Phi_{\xi,n} = 0. \quad (5) $$

Fourier transforms and the operator $C$ are approximated by the FFT on the uniform grid, and all derivatives are performed spectrally (Trefethen 2001). The Jacobian for Newton’s method is computed using

$$ \frac{\partial G_n}{\partial Y_l} = \frac{G_n(Y_1, Y_2, \ldots, Y_l + \delta, \ldots, Y_N) - G_n(Y_1, Y_2, \ldots, Y_l, \ldots, Y_N)}{\delta}, \quad (6) $$

and the stopping criteria for the Newton’s method is

$$ \frac{\sum_{j=1}^N |G_n(Y_1, Y_2, \ldots, Y_N)|}{N} < 10^{-16}. $$

The topography $H(\xi)$ is computed iteratively by solving

$$ X^l_{b}(\xi) = \xi - C \left[ F^{-1} \left( \frac{\hat{Y}(k_j)}{\cosh(k_j D)} - \frac{\hat{H}(k_j)}{\cosh^2(k_j D)} \right) \right] + T \left[ H(k_j) \right], \quad (7) $$

The initial step is $X^0_{b}(\xi) = \xi$ and $H^0(\xi) = h(\xi)$. The scheme is performed with the stopping criteria

$$ \max_{\xi \in [-L, L]} \left| H^{l+1}(\xi) - H^l(\xi) \right| < 10^{-16}. $$

In what follows, we choose the computational domain $[-L, L]$, with $L = 100$ and a uniform grid with $N = 2048$ points. The sensitivity of the scheme with respect to $N$ and $L$ was tested by Flamarion et al. (2019). The authors showed that the solution is accurately captured by different discretizations.

4.1.1 Initial guess for the Newton’s method and topography’s profile

We are interested in studying steady solitary waves solutions for the full Euler equations. It is well known that, in the nearly critical regime ($F = 1 + \epsilon f$, where $f$ is a small parameter) and for obstacles of small amplitudes, the forced Korteweg-de Vries equation

$$ \ddot{\zeta} + f \dot{\zeta} - \frac{3}{2} \dddot{\zeta} - \frac{1}{6} \dddot{\zeta} = \frac{1}{2} h(x), \quad (8) $$

can be obtained asymptotically from Eq. (2). Such equation has been extensively used to investigate the interaction of solitary waves with a external force (Ermakov and Stepanyants 2019; Flamarion and Ribeiro-Jr 2021c; Kim and Choi 2018; Lee and Whang 2015; Lee 2018). In particular, Flamarion et al. (2019) showed numerically solutions of the fKdV equation agree well with the solutions of the Euler equations in the weakly nonlinear weakly dispersive regime. This motivates us to use steady wave solutions of fKdV as initial guess of the Newton’s method. To this end, we proceed in the same fashion as presented by Chardard et al. (2011). We impose

\[
\bar{\zeta}(x) = A \text{sech}^2(\beta x),
\]

to be a steady solution of (8). Thus, the topography satisfies

\[
h(x) = 2f\bar{\zeta} - \frac{3}{2}\bar{\zeta}^2 - \frac{1}{3}\bar{\zeta}_{xx}.
\]

In other words,

\[
h(x) = \frac{A}{6} \left( \frac{12f - 8\beta^2}{\cosh^2(\beta x)} + \frac{12\beta^2 - 9A}{\cosh^4(\beta x)} \right).
\]

Choosing the topographic obstacle to be a sech\(^2\)-type we obtain the two branch of solutions

\[
A = f \pm \sqrt{f^2 - G},
\]

\[
\beta = \sqrt{\frac{3A}{4}},
\]

where \(G\) is the amplitude of the obstacle. Camassa and Wu (1991a,b) showed that the perturbed solitary-wave solution with \(A = f + \sqrt{f^2 - G}\) is always unstable. On the other hand, the perturbed uniform flow solution \(A = f - \sqrt{f^2 - G}\) is stable only if \(G \leq \frac{80}{81}f^2\).

The fKdV variables are related to the Euler’s ones according to the transformations

\[
x \to \epsilon^{1/2}x, \quad t \to \epsilon^{3/2}t, \quad \bar{\zeta} \to \epsilon \bar{\zeta}, \quad h \to \epsilon^{-2}h \quad \text{and} \quad F = 1 + \epsilon f.
\]

We set the topographic obstacle for the Euler equations to be the rescaled topography of the fKdV

\[
h(x) = \epsilon^2 G \text{sech}^2(\epsilon^{1/2} \beta x),
\]

where \(\epsilon > 0\) is a small parameter.

For this choice of topography, it is natural to consider as initial guess for the Newton’s method

\[
Y(\xi) = \epsilon A \text{sech}^2(\epsilon^{1/2} \beta \xi),
\]

where \(A\) and \(\beta\) are determined by Eq. (11) with \(f = 0.32\) and \(G = 0.1\). These solutions are then continued in the parameter \(f\) using the Newton’s Method continuation, which allow us to determine two branch of solutions: solutions of the perturbed solitary-wave and solutions of the perturbed uniform flow.

It is worth to mention that solitary waves can also be computed for flat topographies (\(G = 0\)). The reader is referred to the work of Ifrim and Tataru (2020) for a review of relevant results including the threshold for instability. We point out that our numerical method converges even for small values of \(G\). This behavior can be attributed to the fact that when \(G\) is close to zero, the fKdV equation serves as an asymptotic approximation to
the Euler equations. As a result, the initial guess we use for our Newton’s method becomes highly accurate, due to the use of fKdV solutions as the starting point.

### 4.2 Time-dependent wave solutions

The evolution of the initial data of Eq. (3) is found by integrating in time the family of ordinary differential equations through the fourth-order Runge–Kutta method with time step $\Delta t = 0.01$ and the derivatives in $\xi$ are performed spectrally Trefethen (2001) using the same parameters used to compute the steady waves in the previous section i.e., $L = 100$ and $N = 2048$. The topography $H(\xi, t_m)$ at time $t = t_m$ is computed iteratively by solving

$$X_{b}^{l+1}(\xi, t_m) = \xi - C \left[ \mathcal{F}^{-1} \left( \frac{\hat{Y}(k_j, t_m)}{\cosh(k_j D)} - \frac{\hat{H}^l(k_j, t_m)}{\cosh^2(k_j D)} \right) \right] + T \left[ H^l(k_j, t_m) \right],$$

for $l \geq 0$. Equation (15) is solved using as initial step $X_{b}^0(\xi, t_m) = \xi$ and $H^0(\xi, t_m) = h(\xi)$. The scheme is performed with the stopping criteria

$$\frac{\max_{\xi \in [-L, L]} \left| H_{b}^{l+1}(\xi, t_m) - H^l(\xi, t_m) \right|}{\max_{\xi \in [-L, L]} \left| H^l(\xi, t_m) \right|} < 10^{-16}.$$

This iterative method to compute the topography was used by Viotti et al. (2014) and later its accuracy was investigated by Flamarion and Ribeiro-Jr (2021b).

### 5 Numerical results

In this section, we compute steady solutions using different values of $\epsilon$. The branches of steady solutions is compared with the ones of the fKdV equation. We then perturb the initial data (steady wave) and compute its evolution numerically in order to investigate whether these solutions are stable.

For the fKdV equation, steady waves and their related stability properties were studied in Camassa and Wu (1991a, b) and in Chardard et al. (2011). More recently, Grimshaw and Maleewong (2013) analysed the stability of steady fKdV solutions in both the subcritical ($F < 1$) and supercritical ($F > 1$) regimes. They found steady waves from the transient fKdV solution, whose stability was then analysed through the Euler equations in the presence of a moving pressure distribution. In the presence of a constant current and a topography, Vanden-Broeck (1994) used a boundary integral method to compute steady solutions to the Euler equations. Different steady waves were found, but their stability was not analysed numerically.

Initially, we compute steady solutions using different values of $\epsilon$ through the numerical method described in the previous section. When $\epsilon$ approaches zero and the Froude number is nearly-critical ($F \approx 1$), the two branches (the uniform flow and the solitary-wave) of steady solutions of the full nonlinear model is close to the one predicted by the weakly nonlinear weakly dispersive theory. However, as the Froude number increases, the solitary-wave solutions no longer agree with the solutions of the fKdV model, which does not occur in the uniform flow solutions. More details are given in Fig. 1. As it can be seen, as we allow for a gradual increase of the topography’s amplitude, the solutions of the two models start
to differ and the nonlinear theory predicts solutions of the solitary-wave branch with higher amplitude.

Now, we investigate the wave stability of the steady waves computed through the Newton’s method type by disturbing its initial amplitude and setting it as an initial data for the time-dependent Euler equations (2). It is natural to expect that for small values of $\epsilon$, the results produced by performing numerical simulations with the full nonlinear model to be similar to the ones reported using the fKdV model—for instance, see Chardard et al. (2011).

Figure 2 displays the evolution of a perturbed solution of the uniform flow with $\epsilon = 0.1$. The solution is stable in the sense that, when its amplitude is perturbed, the numerical solution
The wave stability of solitary waves over a bump

Fig. 3 The evolution of the unstable perturbed solitary-wave solution of the Euler equations when $\epsilon = 0.1$ and $F = 1.035$. The initial condition is the steady wave times 1.5 (left) and 0.5 (right).

Fig. 4 The evolution of the stable perturbed uniform flow solution of the Euler equations when $\epsilon = 0.5$ and $F = 1.175$. The initial condition is the steady wave times 1.5 (left) and 0.5 (right).

tend to recover its natural steady state (the decrease in amplitude of the wave on the right of Fig. 2 and the increase in amplitude of the wave on the left of Fig. 2).

Differently from the perturbed uniform flow, the perturbed solitary-wave does not recover its initial state after disturbing its initial amplitude. However, the system is somehow stable in the sense that a perturbed uniform flow solution arises above the obstacle for large times. When the perturbed initial condition has amplitude smaller than the steady solution, its amplitude decreases in time and approaches to the perturbed uniform flow solution. On the other hand, when the perturbed initial condition has larger amplitude than the steady solution, a large solitary wave propagates upstream, leaving behind a small steady wave, which happens to be the perturbed uniform flow solution. These behaviours are depicted in Fig. 3.

Next, we allow the amplitude of the topographic obstacle increases. Fixing $\epsilon = 0.5$, the perturbed solution of the uniform flow turns out to be stable for small perturbation in the amplitude. A typical example is depicted in Fig. 4. The behaviour is qualitatively similar to the one predicted by the fKdV model.
Regarding the solitary-wave perturbed solutions, we see that the weakly nonlinear weakly dispersive model is no longer appropriate to study steady waves, for instance $\epsilon = 0.5$. When the perturbed initial condition has amplitude smaller than the steady solution, its amplitude decreases in time and approaches to the perturbed uniform flow solution. However, when the perturbed initial condition has amplitude larger than the steady solution, its amplitude increases with time towards a value which indicates that this wave may break, which is highlighted in Fig. 5. This behaviour is similar to the ones reported in the works of Grimshaw and Maleewong (2013) and Flamarion et al. (2019) in the context of generated waves by moving disturbances.

6 Conclusions

In this article, we have presented a numerical method to study the wave stability of steady solitary water waves over an uneven topography using a conformal mapping. We showed that the solitary waves perturbed from the uniform flow are always stable while the ones from the perturbed solitary-wave present a certain type of stability when the perturbed initial condition has smaller amplitude and are unstable when the perturbed initial condition has larger amplitude than the steady solution. Besides, we noticed that in the previous case an onset of wave-breaking might occur.

Data availability Data sharing is not applicable to this article as all parameters used in the numerical experiments are informed in this paper.
