SPECTROPHOTOPOLARIMETRY AS A METHOD FOR DETERMINING THE TIME DYNAMICS OF CHANGES IN THE MORPHOLOGICAL STRUCTURE OF MUSCLE TISSUE

Olexandr Harazdiuk¹, Nataliia Kozan², Viktor Kryvetskyi³, Oleksandr Dunaiev⁴

Abstract:
Introduction: The article presents the current state of issues regarding the diagnosis of pathological conditions for forensic medical experts, in particular the study of normal muscle tissue and in the presence of hemorrhages. Particular attention is paid to biophysical research methods with evidence-based accuracy, objectivity, reproducibility, and rapid results.

Objectives: The purpose of the research was to study the possibilities of using spectrophotopolarimetric methods to analyze and determine the relationship of morphological structure of biological tissues with the temporal dynamics of changes in their optical parameters, to establish the possibility of differentiating necrotic changes and signs of damage by applying Mueller matrices of human muscle tissue samples.

Results: During the study, we found a number of features and patterns of change in the properties of the laser beam as a result of passing through biological tissue. Polarization-correlation methods provide new, objective information about the dynamics of change in laser polarimetric imaging of morphological structure of biological tissues. By analyzing the statistical distributions of the ellipticity of polarization of laser images of normal human muscle tissue and in the presence of hemorrhages, the possibility of identifying the relationship between the development of statistically significant changes with increasing time of death and the possibility of differentiating them is considered.

Conclusion: Based on these results, we can conclude that employing laser polarization methods will allow us to open new doors in the study of the biological tissues of the human body. The results showed the effectiveness of the studied methodology and the prospect of further research in this direction.

Keywords: differentiation, muscle tissue, polarization, laser polarimetry, spectrophotopolarymetry, forensic medicine.

Introduction

To date, in studying the morphological features of biological tissues of the human body, researchers are faced with a number of issues, particularly in forensic medicine, that cannot be solved without developing new approaches to the diagnosis of pathological conditions. Recent advances in science, technology, and new diagnostic methods in medicine allow us to find new approaches to solving urgent practical problems. (Carew et al., 2019; Aalders, et al., 2017)

Modern digital techniques for evaluating biological tissues, such as laser polarization techniques, have proven themselves well. (Bachinsky et al., 2020; Garazdyuk et al., 2016; Protsiuk et al., 2020)

According to this methodology, the whole spectrum of biological tissues can be represented as a set of fibrillar protein structures that form their own unique structural and functional organization. An important feature of these proteins is their strict order, which gives them the properties of liquid crystals. Given these facts, biological tissues can be investigated using laser polarimetry methods. (Li, et al., 2017; Ushenko, et al., 2019). These methods provide the most complete information on the polycrystalline structure of biological tissues and fluids of the human body and allow to study the dynamics of changes in different pathological conditions. (Ushenko, et al., 2017; Wang, et al., 2016). A distinctive feature of biophysical research methods is the high sensitivity and the ability to accurately, objectively record the results.

Purpose

The purpose of the research was to study the possibilities of using spectrophotopolarymetric methods to analyze and determine the relationship of the morphological structure of biological tissues with the temporal dynamics of changes in their optical parameters, to establish the possibility of differentiating...
necrotic changes and signs of damage by applying Mueller matrices of human muscle tissue (MT) samples.

**Materials and Methods**

The study was based on a two-component model for describing biological tissue structure: isotropic and anisotropic or crystalline. (Ushenko et al., 2016). The state of polarization of light changes when radiation passes through a sample of biological tissue and when reflected from its surface. The application of laser polarimetry methods in forensic medicine is based on the analysis of these parameters. These techniques provide an analysis of a wide range of parameters, which allows to obtain important information about biological tissues’ morphological structure and properties. (Ushenko et al., 2015; Vanchulyak et al., 2019).

The object of the study was histological sections of human skeletal MT fibers with hemorrhages in these areas and without them (control group), selected from 96 corpses of both sexes. Native histological sections up to 60 mkm thick were obtained from the extracted samples of human MT using a freezing microtome. The studies were carried out using the standard scheme of the spectropolarimeter (Figure 1).

![Figure 1: Structural-logical scheme of the method of azimuthal-invariant mapping of the degree of crystallization of biological layers](image)

| Experimental scheme of the spectropolarimeter: 1- He-Ne laser; 2- He - Cd laser; 3- beamsplitter; 4,5 – mechanical diaphragm; 6 – collimator; 7, 15 – λ1/4 plate; 8, 13 – polarizer; 9, 17, 18 – λ2/4 plate; 10 – BT; 11 – microlens; 12 - λ1/4 plate; 14 - CCD- camera (800x600 pixels); 16 – computer. |

| Source: Authors |

Human muscle tissue samples were illuminated with parallel beams He-Ne laser (λ1 = 0.633 mm, W = 10.0 mBt) and He-Cd laser (λ2 = 0.414 mm, W = 10.0 mBt). The laser beams were sequentially directed to the beam splitter, which made the orientation in the direction of the collimator, which formed a parallel beam of rays (⌀ = 102 mm). The optical path was blocked with mechanical diaphragms in order to achieve alternate illumination with lazars. Polarizing illuminator (for each wavelength consisted of plates λ1/4, λ2/4, and a polarizer) formed linearly polarized laser beams. Polarized images of human MT samples using microlens were projected into the light-sensitive plane of a CCD camera. The methodology of this research method is detailed in the works of Ushenko A.G. et al.

Statistical moments of 1-4 orders of magnitude were used as the main analytical tool for assessing the distribution of random variables that characterize the images and structure of human MT. Calculations were carried out using the following algorithm (Ushenko, et al., 2017; Wang, et al., 2016):

\[
Z_1^\delta = \frac{1}{N} \sum_{i=1}^{N} |J_i| \tag{1}
\]

\[
Z_2^\delta = \frac{1}{N} \left( \sum_{i=1}^{N} J_i^2 \right) \tag{2}
\]

\[
Z_3^\delta = \frac{1}{\left( Z_2^\delta \right)^{\frac{3}{2}}} \left( \frac{1}{N} \sum_{i=1}^{N} J_i^3 \right) \tag{3}
\]
\[ Z_4^d = \frac{1}{(Z_4^d)^2} \left( \frac{1}{N} \sum_{i=1}^{N} J_i^4 \right) \] (4)

**Results**

In control and experimental groups, the polarization structure of laser images at different time intervals after death was studied. A series of polarized laser images of histological sections of MT from the control and experimental groups indicates the presence of a structured grid of optically anisotropic myosin fibrils (Figure 2, 3).

![Figure 2: Three-dimensional reconstruction of the intensity distribution of the laser image of sections of muscle tissue (control group): a) - 6 hours; b) - 24 hours; c) - 48 hours](source: Authors)

Thus, the application of the method of polarization filtering of laser images of human MT opens the possibility of direct study of the structure of their extracellular matrices. The information obtained can objectively assess the processes of temporal dynamics of structural changes in human tissues and identify various pathological conditions. The comparative analysis shows that the value of the extremes of local values of intensity in the area of hemorrhage is much lower than the value in the image of intact areas. This feature can be explained by the more intense absorption of radiation in the area of hemorrhage. Thus, the intensity of the image in such places is less than in areas without hemorrhage.

In order to quantify the identified differences in the statistical and coordinate structure of the distributions of the degree of depolarization, the statistical moments of the 1st - 4th orders were calculated. Table 1 shows the statistical parameters of the distributions of the values of depolarization of laser images of MT, in the presence of hemorrhages and without them, according to the period after death.

![Figure 3: Three-dimensional reconstruction of the intensity distribution of the laser image of sections of muscle tissue with hemorrhages: a) - 6 hours; b) - 24 hours; c) - 48 hours](source: Authors)
The obtained data indicate a high level of sensitivity of this research method to the detection of specific postmortem changes in the protein structure of MT, which is manifested in the change in the anisotropy of the polarization structure of MT images. The probabilities of random values of statistical moments of the 1-2nd order with increasing observation time after death have a pronounced tendency to redistribution to the minimum values, while the values of asymmetry and excess increase (Table 1).

Table 1: Central statistical moments of the 1st - 4th orders characterize the coordinate distributions of the values of polarization parameters of the MT images from the control and experimental groups.

Source: Authors

The obtained data show that the whole set of statistical moments of the coordinate distribution of the values of the laser image of the histological section of the skeletal muscle tissue has reliable and non-zero values. The obtained statistical information about the properties of the histological section of human MT can be used to characterize its properties objectively.

The decrease in the values of statistical moments of the 1-2nd order and the increase in the values of statistical moments of higher orders with increasing time after death can be associated with a decrease in the level of optical anisotropy of MT architecture.

The study revealed a fairly wide range of dynamics of changes in statistical moments of the 1st-4th orders from 1 to 48 hours.

A comparative analysis of the average set of central statistical moments of 1 - 4th orders was performed (Table 2).

The analysis revealed the diagnostic efficiency (statistical reliability ρ < 0.05) of the spectrophotopolarimetric method in the differentiation of MT samples of control and experimental groups.

The obtained results allow us to state that the proposed method is effective in solving a number of forensic issues, in particular the establishment of the presence of damage in the study areas and the time of their occurrence. These issues are extremely important, as they are of crucial medical and legal importance in investigating crimes to establish responsibility for their commission. According to world

literature sources, experts in practice use mostly visual and descriptive methods, and then to clarify the results - histological, histochemical and immunohistochemical methods of research. (Siddiqui et al., 2016; Ibrahim et al., 2019). Siddiqui et al. described the possibility of using a histopathological method to establish a causal relationship between the time of injury and the time of death. In other scientific works, the authors propose an assessment of early molecular changes of miRNAs in damaged areas. (Ibrahim et al., 2019). Similarly, as in our study, the results are based on the detected progressive morphological changes in the areas of damage with increasing interval after death. However, we would like to note that all the above-described techniques, in contrast to laser spectrophotopolarimetry, are quite time-consuming and relatively expensive and depend largely on the researcher's subjective assessment.

Conclusion

Thus, the topographic and statistical structure of maps of polarized images of normal human MT and with hemorrhages was studied. The interval of dynamics of change of statistical moments of the 1st-4th orders from 1 to 48 hours is established. The possibility of statistically significant differentiation of histological samples of MT with and without hemorrhages has been established, which becomes extremely relevant in the practice of a forensic expert in resolving important issues.

Based on these results, we can conclude that the use of laser polarization methods will allow us to open new doors for the study of biological tissues of the human body. The results showed the effectiveness of the studied methodology and the prospects for further research in this direction, in particular the search for relationships between pathological changes in biological tissues and the polarization parameters of their images and architecture.
