Shor’s factoring algorithm illustrates the potential power of quantum computation. Here, we present and numerically investigate a proposal for a compiled version of such an algorithm based on a quantum-wire network exploiting the potential of fully coherent electron transport assisted by the surface acoustic waves. Specifically, a non standard approach is used to implement, in a simple form, the quantum circuits of the modular exponentiation execution for the simplest instance of the Shor’s algorithm, that is the factorization of $N=15$. The numerical procedure is based on a time-dependent solution of the multi-particle Schrödinger equation. The near-ideal algorithm performance and the large estimated fidelity indicate the efficiency of the protocol implemented, which also results to be almost insensitive to small destabilizing effects during quantum computation.

I. INTRODUCTION

Quantum computers can efficiently solve some problems that are unaffordable on classical computers, and processing the information encoded in quantum systems results to be extremely powerful for particular tasks. Specifically, quantum mechanics effects like entan-
lement and wavefunction superposition turn out to be fundamental building blocks, and allow for the quantum computational speedup over classical computation. The Shor’s algorithm has undoubtedly been widely investigated among those illustrating the power of quantum computation. As a matter of fact, it plays a key role in cryptographic protocols, because it allows one to factorize a composite number with a computational time that is a polynomial function instead of an exponential function of the number itself.

The practical implementation of the Shor’s algorithm represents a challenge for quantum information science. Two possible physical architectures have been proposed: nuclear magnetic resonance (NMR) and photonic systems, even though some open questions exist in both cases. While in NMR it is difficult to prepare the qubits in pure states and control their coherent evolution, thus leading to a controversial quantum nature of the experiments, photonic systems cannot be scaled to a larger number of qubits due to their size and stability limitations. Nevertheless, a recent experimental demonstration of Shor’s algorithm was obtained by means of optical waveguides integrated on silica-on-silicon chips. Even if the efficiency of the single photon source and detectors still does not appear to be very good, the suggested architecture is promising for the implementation of large-scale quantum circuits on many qubits.

No evidence of compiled version of quantum factoring algorithm using electron qubits has been achieved so far. The approach of using charge carriers in solid-state systems is very appealing because it does not allow only to overcome the scalability problem, but it also provides a valid guideline for the design of devices easily integrable in the traditional electronic circuitry. Specifically, the possibility to implement Shor’s quantum factoring algorithm on an electronic chip would certainly represent an essential test to verify the potential of quantum cryptography on everyday life.

In this paper, we propose and numerically simulate a compiled version of the Shor’s algorithm. Electronic quantum logic gates in one-dimensional (1D) semiconductor channels are used to realize the necessary processes and to produce multi-particle entanglement and multipath interference. In particular, we have considered the fully coherent Surface-Acoustic-Wave (SAW) assisted electron transport in couples of GaAs quantum wires, with the qubit defined by the localization of a single carrier in one of the coupled channels.

Quantum-wire systems have been shown to be suitable to produce bipartite entangled states and to perform quantum teleportation. Here, the numerical implementation
of the quantum factoring algorithm results to be much demanding in comparison with the previous works [12, 13], due to the higher number of the simulated quantum logic operations over many qubits. Specifically, we design the quantum circuits of the modular exponentiation execution for the easiest meaningful instance of Shor’s algorithm, that is the factorization of \( N = 15 \) for two different co-primes \( C = 11 \) and \( C = 2 \) (defined in Sec. II), corresponding to the period \( r = 2 \) and \( r = 4 \), respectively. The circuit performing the modular exponentiation function is brought to a form different from the one given in literature [1, 4]. This procedure allows one to move on toward simpler networks of electron quantum gates, and aims at future research leading to a scalable full-realization of the Shor’s algorithm in quantum-wire devices. In our implementation the inverse quantum Fourier transformation (QFT) is not present since it is not necessary for any order-2\(^l\) circuit (with \( l \in \mathbb{N} \)), as shown in the literature [7]. For sake of completeness, a description of the circuit realizing the inverse QFT in a quantum-wire network has been given elsewhere [14].

This paper is organized as follows. In Sec. II we illustrate the theoretical features of Shor’s algorithm, while the description of the physical implementation in a quantum-wire device and the discussion of the numerical approach adopted are given in Sec. III. In Sec. IV we show the results obtained from the numerical simulations of two quantum circuits for the factorization of \( N = 15 \) corresponding two different parameters choice. Comments on the results and final remarks are drawn in Sec. V.

II. SHOR’S ALGORITHM

The strategy to find a nontrivial prime factor of the positive integer \( N \) is described in the following. A random co-prime \( C \) is chosen, i.e. \( N \) and \( C \) have not common factors. Euler’s theorem states that exists an integer \( r \) such that \( C^r = 1 \mod N \) (that is, \( C^r - 1 \) is an integer number multiple of \( N \)), with \( 1 \leq r < N \). The number \( r \) is called order of \( C \mod N \). Provided that the latter is even, then it follows that \( C^r - 1 = (C^r/2 - 1)(C^r/2 + 1) = 0 \mod N \) and this implies that \( N \) is a divisor of the product \( (C^r/2 - 1)(C^r/2 + 1) \). Assuming that \( (C^r/2 \neq -1 \mod N) \), it follows that \( N \) must have a common factor with both \( (C^r/2 \pm 1) \). Therefore, this implies that the factors of \( N \) are given by the greatest common divisor of \( N \) and \( (C^r/2 \pm 1) \), which can be efficiently computed by means of Euclid’s classical algorithm. It is worth noting that in order to guarantee the algorithm validity the two conditions stating
that $r$ is even and $(C^{r/2} \neq -1 \mod N)$ must be satisfied. These conditions are met with high probability for $N$ odd, except in the case where $N$ is a prime power ($N = p^\alpha$ with $p$ prime). Thus, the smallest composite integer $N$ that can be successfully factored by Shor’s method is $N = 15$. If $N$ is an even number or a prime power, other classical methods should fruitfully be applied for the factorization instead of the Shor’s method.

The Shor’s algorithm needs quantum computation only in the evaluation of the order $r$. The quantum order-finding routine commonly uses two registers of qubits [1, 3]: the argument register with $n = 2 \ln_2 N$ qubits, and the function-register with $m = \ln_2 N$ qubits. Its implementation can be separated into three distinct steps. The first one is the register initialization corresponding to

$$|0\rangle^\otimes n|0\rangle^\otimes m \mapsto \frac{1}{\sqrt{2^n}}\left(|0\rangle + |1\rangle\right)^\otimes n|0\rangle^\otimes m-1|1\rangle = \frac{1}{\sqrt{2^n}} \sum_{x=0}^{2^n-1} |x\rangle|0\rangle^\otimes m-1|1\rangle,$$

where the argument register is prepared by means of the Hadamard transformations in an equal superposition of all $n$-qubit computational basis $|0(1)_{x_1}\rangle|0(1)_{x_2}\rangle \cdots |0(1)_{x_n}\rangle$. In the second step, also known as modular exponentiation, the function $C^x \mod N$ is implemented on the function register, while the argument register remains in $x$. The global state is thus given by

$$\frac{1}{\sqrt{2^n}} \sum_{x=0}^{2^n-1} |x\rangle|C^x \mod N\rangle.$$

The state of Eq. (2) is highly entangled and exhibits the so-called “massive parallelism”, i.e. the execution entangles in parallel all the $2^n$ input values with the corresponding values of $C^x \mod N$, although the algorithm has run only once [3, 15]. Finally, the inverse QFT is applied on the argument register yielding the state

$$\frac{1}{2^n} \sum_{z=0}^{2^n-1} \sum_{x=0}^{2^n-1} e^{2\pi i x z / 2^n} |z\rangle|C^x \mod N\rangle,$$

where, due to the interference, only the terms $|z\rangle$ with

$$z = a 2^n / r$$

have a significative amplitude. In the above, $a$ is a random integer ranging from 0 to $r-1$. Thus, if one performs measurements on the outcome of the argument register, he would
get $a2^n/r$ for some $a$, and the order $r$ can be deduced after the classical procedure with probability greater than 1/2 (see Ref. [3]).

The modular exponentiation, that is the evaluation of $C^x \mod N$ for $2^n$ values of $x$ in parallel, is the most demanding part of the algorithm. This can be performed by using the identity: $x = x_{n-1}2^{(n-1)} + \cdots + x_12^1 + x_02^0$, where $x_k$ are the binary digits of $x$. From this, it follows that

$$C^x \mod N = C^{2^{(n-1)}x_{n-1}} \cdot \cdots \cdot C^{2x_1}C^{x_0} \mod N = C^{2^{(n-1)}x_{n-1}} \cdots \left[ C^{2x_1} [C^{x_0} \mod N] \mod N \right] \cdots \mod N.$$  \hspace{1cm} \hspace{1cm} (5)

This means that we first multiply 1 by $C \mod N$, if and only if $x_0 = 1$; then we multiply the result by $C^2 \mod N$ if and only if $x_1 = 1$ and so forth, until we finally multiply by $C^{2^{(n-1)}} \mod N$ if and only if $x_{n-1} = 1$. Therefore, the modular exponentiation consists of $n$ serial multiplications modulo $N$, each of them controlled by the qubit $x_k$. The factors $C, C^2, \cdots, C^{2^{(n-1)}} \mod N$ can be found efficiently on a classical computer by repeated squaring.

\begin{enumerate}
\item[a.] \textbf{N=15}
\end{enumerate}

As noted in the previous section, the Shor’s factorization algorithm fails if $N$ is even or a prime power, and the smallest composite integer $N$ that can be successfully factored by means of Shor’s method is $N=15$. Even if $N$ is small, this compiled version of the Shor’s algorithm displays a great potential for a future realization of large-scale quantum algorithm.

Being $N=15$, the minimum size of the function and argument registers must be $m=\ln_2[15]=4$ and $n=2m=8$, respectively. The algorithm would then require at least 12 qubits. However, the following comments allow us to reduce the number of qubits necessary for the purpose of a proof-of-principle demonstration. A co-prime $C$ with 15 is one element of the set 2, 4, 7, 8, 11, 13, and 14. As shown in Table I it comes from repeated squaring that $C^4 \mod 15 = 1$ for all valid $C$. In turn, this implies that only two bits $x_0$ and $x_1$ are needed for the controlled multiplications. As a consequence, the multiplications by $C^4, C^8, \cdots$ are trivial, and all the multiplications, except the ones by $C$ and $C^2$, can be left out. For $C = 4, 11, 14$, $C^2 \mod 15 = 1$ and only the first bit $x_0$ is relevant. These considerations account for a reduction of the size of the argument register, which can finally
| $C$ | 2 | 4 | 7 | 8 | 11 | 13 | 14 |
|-----|---|---|---|---|----|----|----|
| 0   | 1 | 1 | 1 | 1 | 1  | 1  | 1  |
| 1   | 2 | 4 | 7 | 8 | 11 | 13 | 14 |
| $x$ | 2 | 4 | 1 | 4 | 1  | 4  | 1  |
| 4   | 1 | 1 | 1 | 1 | 1  | 1  | 1  |

TABLE I: The table displays $C^x \mod 15$ for all $C < 15$ co-prime with 15 and for values of $x$ which are power of two. Note that $C^4 \mod 15 = 1$ for all valid $C$.

be constituted by no more than two qubits ($n=2$). Adding this latter result to the four qubits of the function register, only six qubits are needed instead of twelve, as previously found.

Shor's factorization algorithm for the number 15 turns out to be particularly simple because it does not require the implementation of the inverse QFT in the quantum circuit. As shown in the literature [7], the latter is not necessary for any circuit of order $2^l$ and it can be replaced by a classical processing which also inverts the order of the computed quantum bits of the argument register.

In this work we implement the Shor’s quantum factoring algorithm and check it against two co-primes: $C=11$ and $C=2$, that are representative parameters for the system at hand.

1. $C=11$

This parameter choice represent an "easy case" since the modular exponentiation can be simplified to the multiplication of the initial function register state, $|y\rangle=|0_{y_3}0_{y_2}0_{y_1}1_{y_0}\rangle=1$, by $C=11$ controlled only by $x_0$.

In the left panel of the Fig. 1 a compiled version of the quantum circuit for $C=11$, using the inverse QFT, is displayed. At first, both registers are initialized: each qubit of the argument is prepared by Hadamard gates in a superposition of 0 and 1, and the function register state is set to $|y\rangle=1$, so that the global state $|\Phi_{C=11}\rangle$ of the system is

$$|\Phi_{C=11}\rangle = \frac{1}{2} (|0_{x_1}0_{x_0}\rangle + |0_{x_1}1_{x_0}\rangle + |1_{x_1}0_{x_0}\rangle + |1_{x_1}1_{x_0}\rangle) \times |0_{y_3}0_{y_2}0_{y_1}1_{y_0}\rangle.$$

(6)
Then, the modular exponentiation is performed: the controlled multiplication of 1 by 11 is equivalent to the controlled addition of 10 to 1. The latter is implemented in the quantum circuit by two controlled-NOT (CNOT) gates: one between \( x_0 \) and \( y_1 \) and one between \( x_0 \) and \( y_3 \). It is worth noting that the qubits \( y_0 \) and \( y_2 \) evolve trivially during computation. Thus the state of the system takes the form

\[
|\Phi_{C=11}\rangle = \sum_{x=0}^{3} |x\rangle|11^x \mod 15\rangle = \\
\frac{1}{2} \times \left( |0_{x_1}0_{x_0}\rangle|0_{y_3}0_{y_2}0_{y_1}1_{y_0}\rangle + |0_{x_1}1_{x_0}\rangle|1_{y_3}0_{y_2}1_{y_1}1_{y_0}\rangle \\
+ |1_{x_1}0_{x_0}\rangle|0_{y_3}0_{y_2}0_{y_1}1_{y_0}\rangle + |1_{x_1}1_{x_0}\rangle|1_{y_3}0_{y_2}1_{y_1}1_{y_0}\rangle \right). \tag{7}
\]

This means that a Greenberger-Horne-Zeilinger (GHZ) entangled state

\[
|\Psi\rangle = \frac{1}{\sqrt{2}} (|0_{x_0}0_{y_3}0_{y_1}\rangle + |1_{x_0}1_{y_3}1_{y_1}\rangle) \tag{8}
\]

is created between qubit \( x_0 \) of the argument register and qubits \( y_3 \) and \( y_1 \) of the function registers.

The final step is represented by the inverse QFT. The right panel of the Fig. 1 shows a compiled version of the quantum circuit without using the inverse QFT. Please note that in this case also qubit \( x_1 \) is redundant: the corresponding Hadamard gate results to be unnecessary and does not need to be implemented. Here, the initial state is \( \frac{1}{\sqrt{2}} (|0_{x_1}0_{x_0}\rangle + |0_{x_1}1_{x_0}\rangle) |0_{y_3}0_{y_2}0_{y_1}1_{y_0}\rangle \) and the modular exponentiation yields \( \frac{1}{\sqrt{2}} (|0_{x_1}0_{x_0}\rangle|0_{y_3}0_{y_2}0_{y_1}1_{y_0}\rangle + |0_{x_1}1_{x_0}\rangle|1_{y_3}0_{y_2}1_{y_1}1_{y_0}\rangle) \).

The outcomes of the measurement on the inverted argument qubits \( x_0 \) and \( x_1 \) give then 00 or 10 with equal probability. Once this result is known, one can obtain the order \( r \) of \( C \) mod \( N \) from Eq. (4). While the output 00 corresponds to a failure, the output 10 allows one to determine the period \( r = 2^2/2 = 2 \) and represents a successful implementation of the Shor’s algorithm.

2. \( C=2 \)

Since the number of gates needed to perform the modular exponentiation is greater than the case of \( C=11 \), the choice of \( C=2 \) represents a “difficult case”. In fact, the modular
exponentiation is given by the multiplication of $|y\rangle=1$ by 2 controlled by $x_0$ and by the multiplication of the obtained result by 4 controlled by $x_1$. The left panel of Fig. 2 shows the quantum circuit for the case at hand. The network for the modular exponentiation is composed of two CNOT followed by two controlled SWAP (CSWAP) gates; the first two correspond to the addition of 1 to $|y\rangle=1$ controlled by $x_0$, while the CSWAP gates multiply the result by 4 controlled by $x_1$. The modular exponentiation leads to the state:

$$
\sum_{x=0}^{3} |x\rangle = 1/2 \times (|0_{x_1}0_{x_0}\rangle|0_{y_1}0_{y_2}0_{y_1}0_{y_0}\rangle + |0_{x_1}1_{x_0}\rangle|0_{y_3}0_{y_2}1_{y_1}0_{y_0}\rangle + |1_{x_1}0_{x_0}\rangle|0_{y_3}0_{y_2}1_{y_1}0_{y_0}\rangle + |1_{x_1}1_{x_0}\rangle|1_{y_3}0_{y_2}0_{y_1}0_{y_0}\rangle).
$$

Nevertheless, a different compilation of the quantum circuit can be realized [7], and it is reported in the right panel of Fig. 2. By means of the latter, it is possible to evaluate $\ln_2 [2^x \mod 15]$ in the function register in place of $2^x \mod 15$, thus reducing the number of function qubits from $\ln_2 [15]=4$ to $\ln_2 \{\ln_2 [15]\}=2$. This compilation maintains all the features of the algorithm originally proposed [3], and still does not make use of the inverse QFT, as in the previous case. Following this scheme, the initialization of the system leads to the state

$$
|\Phi_{C=2}\rangle = \frac{1}{2} \left(|0_{x_1}0_{x_0}\rangle + |0_{x_1}1_{x_0}\rangle + |1_{x_1}0_{x_0}\rangle + |1_{x_1}1_{x_0}\rangle\right)|0_{y_1}0_{y_0}\rangle, 
$$

meaning that the argument register is kept in the usual equally-weighted coherent superposition of all possible arguments, while the initial function register state is $|y\rangle=0$. If we apply the procedure described in Eq. (5) to evaluate $\ln_2 [2^x \mod 15]$, it can be easily shown that

FIG. 1: (Color online). Left panel: Outline of the quantum circuit for quantum factorization of 15 for $C=11$, using the inverse QFT. Right panel: Outline of the quantum circuit for quantum factorization of 15 for $C=11$, not using the inverse QFT.
the modular exponentiation reduces to the sum of \(\ln_2 [2^1 \mod 15] = 1\) to \(|y\rangle = 0\) controlled by \(x_0\), and of \(\ln_2 [2^2 \mod 15] = 2\) to the obtained result controlled by \(x_1\). These operations are implemented in the quantum circuit reported in the right panel of Fig. 2 by means of two CNOT gates: one between \(x_0\) and \(y_0\) and another between \(x_1\) and \(y_1\). It is worth noting that in this case the algorithm is very simple since it consists of only two networks of gates acting on independent qubit pairs. After modular exponentiation the state of the system takes the form

\[
|\Phi_{C=2}\rangle = \frac{1}{2} \left( |0_{x_1} 0_{x_0} 0_{y_1} 0_{y_0}\rangle + |0_{x_1} 1_{x_0} 0_{y_1} 1_{y_0}\rangle + |1_{x_1} 0_{x_0} 1_{y_1} 0_{y_0}\rangle + |1_{x_1} 1_{x_0} 1_{y_1} 1_{y_0}\rangle \right) = \frac{1}{2} \left( |0_{x_1} 0_{y_1}\rangle + |1_{x_1} 1_{y_1}\rangle \right) \left( |0_{x_0} 0_{y_0}\rangle + |1_{x_0} 1_{y_0}\rangle \right),
\]

that is the product of two entangled Bell pairs, thus confirming the manifestation of entanglement between the two registers of the algorithm. The inverse QFT is not necessary and it can be replaced by its classical counterpart, which also swaps the output quantum bit of the argument register. The two-bit outputs for the case under investigations are: 00, 01, 10, and 11. The second and the fourth outcomes allow the evaluation of the order \(r = 4\), which efficiently yields the factors 3 and 5 via Euclid’s classical algorithm; the first one corresponds to a failure mode and, lastly, the third one leads to trivial factors.

### III. THE PHYSICAL IMPLEMENTATION AND THE NUMERICAL APPROACH

Here, we describe the implementation of the Shor’s algorithm in a specific semiconductor nanostructure. It consists of a number of couples of GaAs quantum wires where surface acoustic waves (SAWs), i.e. sinusoidal piezoelectric potential, propagate and trap charged carriers into their moving minima, letting one particle fill in each minimum \[16\]. The so-called flying qubits are realized by means of the states \(|0\rangle\) and \(|1\rangle\), encoded through the localization of a single electron in one of the two 1D channels \[11\]. Here, the SAWs are used to inject and drive the electron thanks to their efficiency in preventing the natural spatial spread of the wavefunction \[17\] and in making the carriers more immune to the decohering effects \[18\]. Moreover, in this investigation the carrier transport is assumed to be fully
As shown in the literature \cite{19,20}, such a system is able to provide the universal set of gates useful to realize any quantum computational network. Specifically, the basic building blocks are $R_x(\theta)$, $R_{0(1)}(\phi)$, and $T(\gamma)$ \cite{21}. The former two gates implement one-qubit logical operations, whereas the latter is a two-qubit gate.

$R_x(\theta)$ acts as an electronic beam splitter and can be materialized through a coupling window between the two wires of the qubit \cite{22}. Its matrix representation on the basis \{$|0\rangle, |1\rangle$\} is given by

$$
R_x(\theta) = \begin{pmatrix} \cos \frac{\theta}{2} & i \sin \frac{\theta}{2} \\ i \sin \frac{\theta}{2} & \cos \frac{\theta}{2} \end{pmatrix}.
$$

(11)

$R_{0(1)}(\phi)$ is an electronic phase shifter obtained by inserting a potential barrier in the wire 0(1), thus inducing a delay phase $\phi$ in the propagation of wavefunction. Its action is described in one-qubit basis by

$$
R_0(\phi) = \begin{pmatrix} e^{i\phi} & 0 \\ 0 & 1 \end{pmatrix} \quad \text{and} \quad R_1(\phi) = \begin{pmatrix} 1 & 0 \\ 0 & e^{i\phi} \end{pmatrix}.
$$

(12)

$T(\gamma)$ is a conditional phase gate exploiting the Coulomb interaction between two electrons. It consists of a region in which the carriers propagate along two different wires close enough to give rise to an effective interaction able to delay both particles. The matrix representation
of $T(\gamma)$ in the two-qubit basis $\{|00\rangle, |01\rangle, |10\rangle, |11\rangle\}$ is:

$$T(\gamma) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & e^{i\gamma} & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}. \quad (13)$$

The phases $\theta$, $\phi$, and $\gamma$ of the above quantum gates depend upon the physical and geometrical parameters of the systems such as velocity, amplitude and wavelength of the SAW potential, strength of the electron-electron interaction, coupling window length, and shape of the potential barrier. In order to perform any transformation of the many-qubit state, an appropriate tuning of the above parameters in a given network of $R_x(\theta)$, $R_0(1)(\phi)$, and $T(\gamma)$ gates is required.

In the compiled versions of the Shor’s algorithm illustrated in the right panels of Figures 1 and 2, corresponding to $C=11$ and $C=2$, respectively, the two logical operations involved are only the Hadamad $H$ and CNOT gates. In terms of $R_x(\theta)$, $R_0(1)(\phi)$, and $T(\gamma)$, these operations can be reworked as [14]:

$$H = R_0 \left( \frac{3\pi}{2} \right) R_x \left( \frac{\pi}{2} \right) R_0 \left( \frac{\pi}{2} \right) R_1(\pi) = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}, \quad (14)$$

and

$$\text{CNOT} = R_0^{(2)} \left( \frac{3\pi}{2} \right) R_x^{(2)} \left( \frac{3\pi}{2} \right) T^{(1,2)}(\pi) R_x^{(2)} \left( \frac{\pi}{2} \right) R_0^{(2)} \left( \frac{\pi}{2} \right) R_1^{(1)}(\pi) = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix}. \quad (15)$$

The numerical implementation of the quantum circuits described in the previous section results extremely challenging due to the large number of basic building blocks needed to realize the $H$ and CNOT gates. Furthermore, the experimental realization of such devices would also certainly meet serious obstacles stemming from the difficulty of preserving the coherent evolution of the qubits during a number of logical operations, from decoherence effects due to interactions with the environment, as well as from possible structural defects induced by the processes of fabrication and tuning of each quantum gate. The theoretical and experimental implementation of two-qubit quantum circuits by means of a minimum
amount of operations has been widely discussed in literature \[23, 24\]. Different protocols have been proposed ranging from the special perfect entanglers \[23\] to the use of a given tunable entangling interaction \[24\]. Here, we propose in the followings a scheme suitable to perform the quantum factoring algorithm in devices formed by semiconductor quantum wires with a minimal number of the fundamental gates $R_x(\theta)$, $R_{0(1)}(\phi)$, and $T(\gamma)$. The proposed implementation satisfies the main requirements of the Shor’s algorithm as originally formulated \[1, 3\]. In fact, “massive parallelism” is maintained, since entanglement is created between argument and function registers, and the binary output of the argument qubits are unchanged, as it will be shown below. In the left and right panel of the Fig. 3 we report the quantum-wire networks implementing the circuits displayed in the right panels of Figures 1 and 2 respectively.

In the first case, corresponding to $C=11$, the network implemented reads

$$R_x^{(x_0)}\left(\frac{\pi}{2}\right) R_x^{(y_1)}\left(\frac{\pi}{2}\right) T^{(x_0,y_1)}(\pi) R_x^{(y_1)}\left(\frac{\pi}{2}\right) R_x^{(y_3)}\left(\frac{\pi}{2}\right) R_{0}^{(y_1)}(\pi) T^{(y_1,x_0)}(\pi) R_1^{(x_0)}(\pi) R_x^{(y_3)}\left(\frac{\pi}{2}\right) \ ,$$

where the superscripts of the quantum gates indicate which qubit they act on. The three-qubit output state is:

$$\frac{1}{\sqrt{2}} (-|0_{x_0}0_{y_3}0_{y_1}\rangle + i|1_{x_0}1_{y_3}1_{y_1}\rangle) \ . \quad (16)$$

For $C=2$ the global logical transformation can be written as:

$$R_x^{(x_0)}\left(\frac{\pi}{2}\right) R_x^{(y_0)}\left(\frac{\pi}{2}\right) R_x^{(x_1)}\left(\frac{\pi}{2}\right) R_x^{(y_1)}\left(\frac{\pi}{2}\right) T^{(x_0,y_0)}(\pi) T^{(x_1,y_1)}(\pi) R_x^{(y_0)}\left(\frac{\pi}{2}\right) R_x^{(y_1)}\left(\frac{\pi}{2}\right) \ ,$$

and, after being applied to the input state $|0_{x_1}0_{x_0}0_{y_1}0_{y_0}\rangle$, it yields

$$\frac{1}{2} \left( |0_{x_1}0_{y_1}\rangle - |1_{x_1}1_{y_1}\rangle \right) \left( |0_{x_0}0_{y_0}\rangle - |1_{x_0}1_{y_0}\rangle \right) . \quad (18)$$

In both cases, the degree of the entanglement created between the qubits of the argument and the function register is equal to the one of the standard formulation of Shor’s quantum factoring algorithm \[1, 3\]. While for $C=11$ the output state is GHZ-like, i.e. the maximum amount of quantum correlations is built up among three qubits, when $C=2$ the four qubit-state is the product of two entangled Bell pairs. Furthermore, the reduced density matrices of the argument qubits correspond to the ones calculated from the quantum states of Eqs. (8) and (10). In turn, this implies that the binary output of the algorithm, i.e. the outcome measurements on the argument register, be identical.
FIG. 3: (Color online). Left panel: Sketch of the physical system used to factorize $N=15$ with $C=11$, corresponding to the quantum circuit displayed in the right panel of Fig. 1. The beamsplitter $R_x$ of the qubit $x_0$ mimics the initialization procedure, that is the equal splitting of electron wavefunction of the qubit $x_0$ in the two wires. The next two sets of gates, first $R_xTR_x$ acting on $\{x_0, y_1\}$ and then $R_xR_0TR_1R_x$ on $\{x_0, y_3\}$, play the role of two CNOT gates creating the maximum entanglement of the qubits $\{x_0, y_1, y_3\}$ in the modular exponentiation step. For sake of clarity the qubits $y_0$ and $y_2$ evolving trivially during the computation have not been reported.

Right panel: Sketch of the physical system used to factorize $N=15$ with $C=2$, corresponding to the quantum circuit displayed in the right panel of Fig. 2. In the initialization procedure two gates $R_x$ act on the the couple of the argument register qubits $\{x_0, x_1\}$ and split each of them in an equal superposition of the $|0\rangle$ and $|1\rangle$ states. The modular exponentiation consists of two network $R_xTR_x$, each operating onto $\{x_0, y_0\}$ and $\{x_1, y_1\}$ mimicking the action of two CNOT gates. Note that here, for brevity, the phases of the quantum gates involved in the networks and explicitly indicated in the Eqs. (16) and (18), are omitted.

The networks of the gates described in Eqs. (16) and (18) have been simulated by solving numerically the time-dependent Schrödinger equations for three and four electrons injected in the GaAs quantum wire devices of Fig. 3. While for $C=2$ the four-particle dynamics reduces to the time evolution of a pair of separable two-particle systems, when $C=11$, a solution of the Schrödinger equation for the whole three-carrier wavefunction is required. Anyway, in order to minimize the computational burden of both of the reported cases, a semi-1D approach has been used to investigate the time evolution of the system in place of a two-dimensional (2D) computational scheme. This approach was already introduced to simulate a teleportation protocol in a quantum wire device. According to this simplified scheme,
the direction \( y \) of the particles along the wires is fully included in the simulation (\( y \) being discretized with a point-grid resolution of \( \Delta y = 1 \text{nm} \)), while the two variables describing the longitudinal direction \( x \) and identifying the wire where the carriers are localized can only assume one of the two values 0 or 1.

Though it does not allow to simulate the gate \( R_x(\theta) \), which would require a full 2D analysis, the numerical procedure here adopted makes it possible to move from a time dependent Schrödinger equation for a multi-variable wavefunction \( \Phi(\mathbf{X}, \mathbf{Y}, t) \) (seven unknowns for the device with \( C = 11 \) and nine when \( C = 2 \)) to many coupled Schrödinger equations of the following kind:

\[
i \hbar \frac{\partial}{\partial t} \Phi(\mathbf{X}, \mathbf{Y}, t) = \left( -\frac{\hbar^2}{2m} \nabla_\mathbf{Y}^2 + V(\mathbf{X}, \mathbf{Y}, t) \right) \Phi(\mathbf{X}, \mathbf{Y}, t),
\]

(20)

where \( \mathbf{X} \equiv (x_{x_0}, x_{y_0}, x_{x_1}, x_{y_1}, \ldots) \) and \( \mathbf{Y} \equiv (y_{x_0}, y_{y_0}, y_{x_1}, y_{y_1}, \ldots) \). Specifically, when \( C = 11 \) a system of eight coupled equations is obtained, while for \( C = 2 \) two independent systems of four equations are found since the qubit pairs \( \{x_0, y_0\} \) and \( \{x_1, y_1\} \) are independent. In both the cases a Crank-Nicholson finite difference scheme \[26\] has been applied to get a numerical solution. The potential term \( V(\mathbf{X}, \mathbf{Y}, t) \) appearing in Eq. (20) sums up the SAW time dependent potential, the Coulomb interaction between electrons, and the static potential profile. The simulations here presented make use of a sinusoidal potential mimicking a SAW of amplitude and wavelength equal to 20 meV and 200 nm, respectively, and propagating with the sound velocity \( v_s = 3.3 \times 10^3 \text{ m s}^{-1} \). Screening effects have been included in the Coulomb potential between the carriers by inserting an exponential damping term \[27\] with a Debye wave vector of 0.2 nm\(^{-1}\).

In order to numerically implement the networks described in Eqs. (16) and (18), one must firstly to find the suitable geometrical parameters of the device for the gates \( R_0(\phi) \) and \( T(\gamma) \) giving the required value \( \pi \) of the phases \( \phi \) and \( \gamma \). To this aim, we have performed a number of simulations testing different geometries for the phase shift and the conditional phase gate. As to the phase \( \phi \) is concerned, it depends on the height and the length of the potential barrier. The values of these parameters obtained from the optimization procedure are 2.82 meV and 8 nm, respectively, and correspond to a delay phase \( \phi \) of 0.92\( \pi \), that is good enough for our purposes, as it will be shown in the next section. It is worth noting that the barrier height is significantly smaller than the amplitude of the SAW potential, this making the spatial spreading of the electron wavepacket negligible and letting it be entirely
transmitted through the barrier. The main geometrical parameters affecting the phase $\gamma$ of the conditional phase gate are the length of the coupling region and the distance between the coupled wires. Their optimal values used in the numerical implementation of the algorithm are 150 nm and 5 nm, respectively. They lead to a $\gamma$ value about $0.88\pi$, which allows us to simulate satisfactorily the two-qubit logical operation of a CNOT-like gate. By applying the described geometry for $T(\gamma)$, both the tunnelling effects between the two wires and the reflection phenomena in the coupling region are negligible.

From a computational point of view, the numerical simulation of the $T(\gamma)$ gate is more challenging than that of the phase shift $R_0(1)(\phi)$. While the latter involves a one-particle potential, the former exploits a two particle-interaction that builds up an amount of quantum correlations between the wire degrees of freedom of the particles, as expected. However, it creates also an undesired entanglement between the variables defining the position of the carriers along the wires. As a consequence, the evaluation of the effects of the controlled phase gate on the multi-particle wavefunction is a demanding task because it implies that a number of two particle simulations must be combined together to obtain the time-evolved state of the overall system.

The $R_x(\theta)$ gate has not directly been simulated; nevertheless, its action has been taken into account by means of the transformation matrix of Eq. (11), validated by the results of appropriate 2D simulations [20].

IV. RESULTS

According to the sectioning of the previous paragraphs, we firstly present the results obtained for $C=11$, then those for $C=2$.

A. $C=11$

Figure 4 shows the density matrix describing the qubits of the argument and function register, $\{x_0, y_1, y_3\}$ at three different stages: input, initialization procedure and modular exponentiation. For sake of simplicity, we do not consider the $x_1$, $y_0$, and $y_2$ qubits that evolve trivially during the computation. The knowledge of the joint state of both registers after modular exponentiation is essential for the estimation of the device performance. In
FIG. 4: (Color online). The density matrix of the qubits \( \{x_0, y_1, y_3\} \) evaluated at three different time steps: a) input, b) initialization procedure, and c) after the modular exponentiation. Note that these matrices have been obtained from the full density matrices of the electrons of the qubits \( \{x_0, y_1, y_3\} \) by integrating over the variables defining the position of three carriers along the channels. Here the moduli of the density matrix elements are plotted.

particular, we find that the output quantum state corresponds to the GHZ-like entangled state \(|\Psi\rangle\) of Eq. (17) with a good approximation. For a more quantitative evaluation of the reliability of the algorithm, we have also calculated the fidelity \( F = \langle \Psi | \rho_{\text{out}} | \Psi \rangle \), where \( \rho_{\text{out}} \) is the output density matrix of the full system. The high value found, \( F=0.97 \), evidences the very good efficiency of the implementation. Such a result is certainly related to the fact that our numerical simulations have been performed by setting the device temperature at 0 K, that is neglecting any effect of decoherence induced by the environment on the carrier transport properties. In particular, this means that the electron-phonon interaction have not been included in the simulations. These assumptions are physically sound when we take into account that the experimental investigations of the low-dimensional structures used as the basic blocks for our device are usually performed at very low temperatures [10, 22]. Moreover, one of the pros of our results certainly relies on the high fidelity value, which has not been obtained under ideal geometries for the \( R_0(1)(\phi) \) and \( T(\gamma) \) gates. Once more, this off-ideality situation is close to the experimental conditions.

The density matrix of the argument register after modular exponentiation is displayed in Fig. 5. Specifically, we show the reduced density matrix \( \rho_{\{x_0,x'_0\}}(y,y) \) of the electron of qubit \( x_0 \), without the redundant qubit \( x_1 \). The output of the quantum circuit is the logical state probability, that is the probability of finding the electron of the qubit \( x_0 \) in the wire 0 or 1. This is described by the integral over \( y \) of the diagonal elements of \( \rho_{x_0,x'_0}(y,y) \). The off-diagonal terms are very small, thus proving that the argument register becomes a
full quantum statistical mixture because of its entanglement with the function register. To better quantify the amount of the quantum correlations created between \( x_0 \) and \( \{y_1, y_3\} \), we evaluate the linear entropy \( \varepsilon_L \) of the qubit \( x_0 \) as \[28\]: \[ \varepsilon_L = 2 \left( 1 - \text{Tr} \rho_2^2 \right) \], where the factor 2 stems out from the normalization condition and \( \rho_2^2 \) is the square of the reduced density matrix \( \rho_{\{x_0, x'_0\}}(y, y) \) of the electron of the qubit \( x_0 \) integrated over \( y \). We find that \( \varepsilon_L = 0.999 \) and therefore a maximal correlation between the two registers of the quantum circuit is build up, that unambiguously proves the quantum nature of the simulated circuit, as required by Shor’s algorithm. Once the logical state probabilities of the qubit \( x_0 \) are known, the latter are combined with the qubit \( x_1 \) in the zero state and then, as required, the order of the argument bits is inverted. This procedure allows one to obtain the binary output of the circuit already discussed in Sect. II A 1, namely 00 and 10. The first is found with a probability of 50.1\% and represents the expected failure of the Shor’s algorithm, whereas the second is obtained with a 49.9\% probability and leads a to successful determination of the order \( r \). As theoretically expected [1, 3], failure and success have equal probabilities. These outputs indicate an almost ideal performance of the quantum algorithm.

![Graphical representation](image)

FIG. 5: (Color online). Density matrix \( \rho_{\{x_0, x'_0\}}(y, y) \) of the electron of qubit \( x_0 \) after the modular exponentiation. The diagonal elements describe the density probability of finding the electron in the point \( y \) along the wire 0 or 1. Here the moduli of \( \rho_{\{x_0, x'_0\}}(y, y) \) are plotted. Note that the curves reported in the left panels refer to the left ordinate axes, while the ones reports in the right panels refer to the right ordinate axes.
B. \( C=2 \)

The numerical investigation of the compiled version of Shor’s algorithm with \( C=2 \) and the evaluation of the function \( \ln_2[2^{x \mod 15}] \) in the function register required the evaluation of the time evolution of all of the qubits of the registers: \( x_0, x_1, y_0, y_1 \). The density matrix describing the global system is displayed in Figure 6 at three different time steps. The output quantum state describes, with a fidelity of 0.89, the product of two maximally entangled Bell pairs, as theoretically expected. The argument register outputs are reported in Figure 7, where the reduced density matrix \( \rho_{\{x_0,x_1,y_0,y_1\}}(y,y',y'',y''') \) of the couple of the electrons of qubits \( \{x_0, x_1\} \) is displayed. The argument register is almost maximally mixed as a consequence of the entanglement with the qubits \( \{y_0, y_1\} \), as the large value of the linear entropy \( \varepsilon_L = 0.976 \) confirms. The binary output of the algorithm, namely one among the possible two-bit responses 00, 01, 10 and 11, is obtained by considering the probabilities of the logical state of the qubits \( \{x_0, x_1\} \) and then inverting their order. The second and the fourth terms yield \( r=4 \), which gives correctly the factors 3 and 5 once processed in the classical Euclid’s algorithm; on the contrary, the first value corresponds to a failure mode whereas the third one leads to trivial factors. All of the outcomes have exactly the same probability to happen, which consequently means that the routine has a success rate of 50% like the previously-discussed case of \( C=11 \).

Although the binary outputs of the argument registers clearly indicate that the algorithm performance is near-ideal both for \( C=11 \) and \( C=2 \), the efficiency of the quantum networks

![FIG. 6: (Color online). The density matrix of the qubits \( \{x_0, x_1, y_0, y_1\} \) evaluated at three different time steps: a) input, b) initialization procedure, and c) after the modular exponentiation. Note that these matrices have been obtained from the full density matrices of the electrons of the qubits \( \{x_0, x_1, y_0, y_1\} \) by integrating over the variables defining the position of three carriers along the channels. Here the moduli of the density matrix elements are plotted.](image-url)
FIG. 7: (Color online). Density matrix $\rho_{\{x_0,x'_0,x_1,x'_1\}}(y,y',y')$ of the couple of electrons of qubit $\{x_0,x_1\}$ after the modular exponentiation. The diagonal elements describe the density probability of finding the two electrons in the points $y$ and $y'$ along the wire 0 or 1. Here the moduli of $\rho_{\{x_0,x'_0,x_1,x'_1\}}(y,y',y')$ are plotted.

is slightly different in the two implementations investigated, as evidenced by the estimated fidelity and degree of entanglement between the registers. More specifically, the quantum circuit performance gets worse moving from $C=11$ to $C=2$. Such a behavior, at a first sight, appears to be surprising, due to the larger number of one- and two qubits quantum gates numerically simulated in the former implementation. A possible explanation could amazingly bring up the small errors inherent the tuning of the quantum gates. In fact, the
flaws of the one- and two-logical operations could counterbalance each other resulting as a net effect a higher efficiency of quantum circuits.

V. CONCLUSIONS

Shor’s algorithm highlights the potential power of quantum computation and nowadays its realization in scalable structures represents one of the main challenges of quantum information science. Only in recent years experimental demonstrations of this algorithm have been given in some physical scenarios ranging from NMR to photon qubits. Nevertheless, the quantum nature of the processes and/or the scalability of the investigated systems in these approaches are questionable.

In this paper we have introduced and numerically simulated an implementation of the easiest meaningful example of the Shor’s algorithm, that is the factorization of \( N=15 \), through co-primes \( C=11 \) and \( C=2 \). The idea we have proposed exploits the coherent SAW-assisted transport of electrons in networks of coupled quantum wires, and has a great potential in view of its integrability with conventional microelectronics and of its scalability to more complex systems containing many qubits. Quantum information is processed by means of a sequence of one- and two-qubit gates, materialized by means of an electronic beam splitter and phase shifter and a Coulomb coupler, respectively. Their experimental realization in semiconductor quantum wires is very challenging since it requires the use of frontier semiconductor technology. Only in the last years, prototype blocks mimicking single-qubit rotations in a couple of 1D channels have been experimentally demonstrated \[22, 29, 30\]. In particular, the switching of coupled-quantum wire qubit characteristics has been explored \[22\]. Furthermore, Fischer et al. controlled the coupling between two modes of a couple of 1D channels, obtained exploiting the two minima of the conduction-band edge in the growth direction of a GaAs 2D electron gas \[30\] or two vertically-coupled 2D electron gases \[29\]. No experimental evidence of two-qubit operation in quantum wires networks has been achieved so far. On the other hand, the coherent manipulation of charge states in two spatially separated double quantum dots integrated in a GaAs/AlGaAs heterostructure has been realized \[31, 32\]. Specifically, two-qubit operations (swap and controlled-rotation) have been successfully implemented.

We stress that the protocol here proposed for the order-finding routine at the heart of
Shor’s algorithm represents a “non standard” implementation of the quantum circuits as commonly used in the literature for quantum factorization [1, 4]. Such an implementation keeps the basic features of the original algorithm (i.e., “massive parallelism” given by the entanglement between the quantum registers and binary output), and also allows for a simple network with a lower number of fundamental gates. This makes the numerical simulation of the presented protocol less demanding and could also have interesting perspectives on the full-scale realization of Shor’s algorithm.

The high efficiency of the quantum processes simulated is shown by the large values obtained for fidelities. Furthermore, also the success rate of the algorithm are close to its ideal value, in agreement with recent experimental investigations [7]. The algorithm performance is even more noteworthy if we do consider the good but not ideal geometry of the logic gates and compare our data with those of the near-ideal case. This behavior is a clear signature of the robustness of the algorithm, which is also able to accommodate small, but non negligible errors coming from the fabrication and tuning of the quantum gates. The capability to take into account small deviations from ideality is certainly a plus, that makes the algorithm to compare favourably to any of its experimental implementations. In fact, it gives the opportunity to let the device work correctly even in presence of unavoidable environmental decoherence effects, always present even at low temperatures.

Since the recent developments in nanostructure fabrication opened new scenarios in scalable electronic quantum computation [10, 29, 33], the promising results here presented indicate a fruitful guideline for the research in quantum information science. Specifically, this work highlights a peculiar physical architecture which could become, in a near future, a powerful mean to implement a broader variety of quantum algorithms and therefore to fully exploit the whole potential of quantum computation.
