Dimensional Crossover in Quantum Antiferromagnets

The dimensional crossover in a spin-$S$ nearest neighbor Heisenberg antiferromagnet is discussed as it is tuned from a two-dimensional square lattice, of lattice spacing $a$, towards a spin chain by varying the width $L_y$ of a semi-infinite strip $L_x \times L_y$. For integer spins and arbitrary $L_y$, and for half integer spins with $L_y/a$ an arbitrary even integer, explicit analytical expressions for the zero temperature correlation length and the spin gap are given. For half integer spins and $L_y/a$ an odd integer, it is shown that the $c = 1$ behavior of the $SU(2)_1$ WZW fixed point is squeezed out as the width $L_y \to \infty$; here $c$ is the conformal charge. The results specialized to $S = 1/2$ are relevant to spin-ladder systems.

PACS: 75.10.Jm, 75.10.-b

One-dimensional quantum antiferromagnets have many unusual properties. For example, nearest-neighbor Heisenberg spin chains with half integer spins are gapless, but those with integer spins are generically gapful [1]. Many properties, such as these, can be understood from the correspondence of the spin chain to a $(1+1)$-dimensional $O(3)$ non-linear $\sigma$-model, augmented by a term in the action that contributes a phase factor $e^{i\theta Q}$ to the path integral, where $\theta = 2\pi S$ ; $S$ is the spin, and $Q$ is an integer winding number. For integer spins, $\theta = 0 \mod (2\pi)$, the phase factor is unity, but for half-integer spins, $\theta = \pi \mod (2\pi)$, it is $(-1)^Q$. This leads to the crucial difference between the integer and the half-integer spins. Although the existence of the gap in the model with $\theta = 0$ can be seen in a variety of ways [2], the model with $\theta = \pi$ is more subtle [3]. For $\theta = \pi$, the short distance behavior is dominated by two weakly interacting Goldstone modes. These are correctly described by the perturbative renormalization group analysis that is insensitive to the existence of the $\theta$-term. In the language of conformal field theory, the system is in the proximity of an infrared unstable fixed point corresponding to conformal charge $c = 2$. At short distances, there is no distinction between integer and half integer spins, and the system appears gapful. However, on longer scales, the $\theta = \pi$ model flows to $k = 1$ $SU(2)$ Wess-Zumino-Witten model ($SU(2)_1$ WZW), corresponding to a $c = 1$ massless theory. Indeed, all critical theories in two dimensions must belong to a conformally invariant fixed point.

The two-dimensional square-lattice, nearest neighbor Heisenberg antiferromagnet is entirely different. It is rigorously known that the ground state is Néel ordered for $S \geq 1$ [4], but no such proofs exist for $S = 1/2$. Nonetheless, the numerical evidence for an ordered ground state for $S = 1/2$ is strong [5]. Moreover, the assumption of an ordered ground state has yielded predictions [6] that are confirmed in neutron scattering experiments [7]. Henceforth, I shall assume that this is also a solved problem, and the correct low energy theory is a $(2+1)$-dimensional $O(3)$ non-linear $\sigma$-model, which is in the broken symmetry phase in its ground state [8]. (The possible existence of topological terms were considered and discarded by a number of authors [9].) The corresponding elementary excitations are weakly interacting Goldstone modes, that is spin waves. This low-energy, long wavelength model is essentially geometrical and is almost entirely determined by symmetry [10] regardless of whether or not the magnitude of the spin is large. The two needed phenomenological constants are the spin wave velocity and the spin stiffness constant. In principle, experiments can determine these constants and there is no need to rely on a presumed large-$S$ expansion.

It is an intriguing question to ask how a two dimensional system would evolve if we began with a strip, $L_x \times L_y$, and continuously tuned the system by varying the width $L_y$, with $L_x$ kept infinitely large. Would it approach the one-dimensional limit, and, if so, how would we recover the sensitivity to the topological angle $\theta$? This would be of only theoretical interest, albeit considerable interest, if it were not for experiments on spin ladders [11] in which $S = 1/2$ systems of varying width are explored. The purpose of the present paper is an attempt to clarify this crossover and to determine the evolution of the excitation spectrum.

It has been argued [12] that spin ladders correspond to an effective $(1+1)$-dimensional $O(3)$ non-linear $\sigma$-model with the $\theta$-parameter given by $\theta = 2\pi n_l S$, where $n_l$ is the number of legs. Thus, for $S = 1/2$, the system is gapful for even-leg ladders and gapless for odd-leg ladders in accord with experiments [13]. There are complimentary theoretical and numerical approaches to the ladder systems that are outside the scope of the reasoning in this paper [14]. However, the crossover problem stated above has not been fully elucidated, although it was anticipated [15] that, when approached along the sequence of even-leg ladders, the gap must collapse exponentially with the increasing width of the system. In the present paper, I shall show precisely how this happens and de-
rive a formula that can be checked. At first sight, the approach to the two-dimensional limit along the odd sequence appears to be simple, because they are gapless. However, this is not so because the two-dimensional problem, which is insensitive to topology, is described by two Goldstone modes; it cannot be a straightforward extension of the $c = 1$ fixed point of the $SU(2)_1$ WZW model.

The Euclidean action of the $O(N)$ quantum non-linear $\sigma$-model, in which one of the dimensions is singled out and is of finite extent $L$, is

$$\frac{S}{\hbar} = \frac{\rho_0}{2\hbar} \int_0^{\beta \hbar} d\tau \int d^{d-1}x \int_0^L dx_1 \left[ (\partial_\mu \vec{\Omega})^2 + \frac{1}{c^2} \left( \frac{\partial \vec{\Omega}}{\partial \tau} \right)^2 \right],$$

(1)

where the index $\mu$ runs over all the spatial dimensions, 1 through $d$. The extent of the imaginary time dimension, $\beta \hbar$, tends to infinity as the temperature $T = 1/k_B \beta$ tends to zero. We shall impose a periodic boundary condition along the direction 1; the remaining spatial directions will be assumed to be infinite in extent. The staggered order parameter field of the antiferromagnet, $\vec{\Omega}$, is an $N$-component unit vector field, which is a function of $(\tau, x_1, x_2, \ldots, x_d)$; the spin-$S$ antiferromagnet corresponds to $N = 3$. The parameter $\rho_0$ is the bare spin stiffness constant at the spatial cutoff, $\Lambda^{-1}$, of the model, and the parameter $c$ is the spin wave velocity on the same scale. I shall focus on the zero temperature behavior and report results of a “Lorentz” invariant analysis; therefore, the spin wave velocity will not renormalize.

The action at $T = 0$ is interesting. The extents in all directions, except $x_1$, are infinite; along $x_1$ we have a periodic boundary condition. The physical problem at $T = 0$ is, therefore, isomorphic to a problem at finite “temperature”, where the temperature-like variable is $\varepsilon_L = \hbar c / L$. With proper identifications of the parameters, it is identical to that solved in Ref. [3]. Let us define two dimensionless bare coupling constants:

$$g_0 = \frac{\hbar c \Lambda^{d-1}}{\rho_0^2},$$

$$\varepsilon^0_L = \frac{\hbar c \Lambda^{d-2}}{L \rho_0^2}.$$  

(2)

The energy-like parameter $\varepsilon^0_L$ plays the role of the dimensionless temperature-like coupling constant in Ref. [3], and $g_0$ is the same as that defined previously.

The renormalization group equations can be simply read off from Ref. [3]. The crossover phase diagram, in $d = 2$, constructed from these equations is shown in Fig. 1, merely for orientation. The three distinct regions had to be renamed, as the present analysis corresponds to $T = 0$. The regions previously named “renormalized classical”, “quantum critical”, and “quantum disordered” are now renamed to be “dimensionally reduced”, “critical spin liquid”, and “gapped spin liquid”, respectively. With simple transcriptions, the physical pictures of the crossover boundaries are the same as before. The analyses of the gapped and the critical spin liquid regimes are exceedingly complex and are beyond the scope of the present paper.

The region of the phase diagram for which we can make precise predictions is the dimensionally reduced region. In this region, the system is in the Néel ordered state when $L = \infty$, or $\varepsilon_L = 0$. When $L \neq \infty$, the system is equivalent to a dimensionally reduced effective $(1 + 1)$-dimensional model with no long range order. This can be seen from the renormalization group equations [14]. At first, with increasing length scale, $g$ rapidly decreases, and $\varepsilon_L$ increases slowly, that is, the system appears more and more ordered. Subsequently, the growth of $g$ slows down, but $\varepsilon_L$ increases more rapidly, thereby breaking up the order at longer length scales, resulting in the reduction from $(2 + 1)$ to $(1 + 1)$ dimensions. The effective coupling constant to be used in the $(1 + 1)$-dimensional model is easily calculated to be

$$\frac{1}{\varepsilon_{\text{eff}}} = \frac{L}{\hbar c} \rho_s \left[ 1 + \frac{\hbar c}{2\pi L \rho_s} \ln(\Lambda L) \right],$$

(3)

where $\rho_s$ is the fully renormalized macroscopic spin stiffness constant at $T = 0$ of the square-lattice spin-$S$ antiferromagnetic Heisenberg model ($L_x = \infty, L_y = \infty$) [14]. This definition can be made more explicit, if we recall that $\rho_s = JS^2 Z_{\rho_s}$, and $\hbar c = 2\sqrt{2} JS a Z_c$, where $J$ is the exchange constant, $a$ is the lattice spacing; $Z_{\rho_s}$ and $Z_c$ are the renormalization factors [14]. We can now write

$$\varepsilon_{\text{eff}} = \frac{2}{S} \left[ \left( \frac{Z_{\rho_s}}{\sqrt{2} Z_c} \right) \frac{L}{a} + \frac{1}{\pi S} \ln(\Lambda L) \right]^{-1}.$$  

(4)

Therefore, for large $(L/a)$, the input bare coupling constant to the effective $(1+1)$-dimensional model is greatly

\[ FIG. 1. The crossover phase diagram in d = 2. \]
reduced from its value \((2/S)\) of a spin chain. This is due to increased order at short distances, concomitant of the quasi two-dimensional nature of the model with finite width \(L\).

For integer spins, and for even-legged ladders with half integer spins, the description of the dimensional crossover is conceptually complete. The system is massive and its mass gap should be calculated with the effective coupling derived above. I shall make more precise predictions later. The case of odd-legged ladders with half integer spins requires further clarification. Because all possible topological terms were dropped in the \((2 + 1)\)-dimensional model, the masslessness of the dimensionally reduced system could not be recovered. Even in the presence of sufficiently strong local Néel order, the proof of the nonexistence of the topological term in \(d = 2\) is correct strictly when the number of spins along both \(L_x\) and \(L_y\) are even. For odd number of chains along \(L_y\), but \(L_x = \infty\), a topological term \(2\pi SQ\) remains \(\xi/\hbar c\). If we wish, we can rewrite it as \(2\pi SQ \xi_1\) by realizing that the topological angle is only defined modulo \(2\pi\). It has been never fully explained why this odd-chain case is physically irrelevant; in fact, it is not, as we shall see. Imagine that we include such a term in our action \(\mathcal{H}\). For finite \(L\), this should, in principle, render the model massless in the sense of a Goldstone phase. However, the \(c = 1\) behavior will be difficult to see when \(L/a\) is large. The reason is that the effective coupling constant defined in Eq. (4) will be very small, and the perturbative renormalization group, which is impervious to the topological term, will be valid up to very long distances, until the coupling constant becomes of order unity for the system to crossover to \(c = 1\) \(SU(2)_1\) WZW model. Recall that the \(\theta = \pi\) model in \((1 + 1)\) dimensions is massless but not conformally invariant; it has a non-trivial \(\beta\)-function and an associated mass gap. Thus, the region in which the \(c = 1\) behavior is seen is squeezed out as \(L \to \infty\), and all we see is the Goldstone phase; we shall see that the mass gap vanishes exponentially as \(L \to \infty\). Conversely, when \((L/a)\) is of order unity, the \(c = 1\) feature should be visible.

Using Ref. [1], it is possible to write down by inspection the expression for the correlation length, \(\xi\), in our \(O(3)\) model defined on a strip for which \(L_x = \infty\), \(L_y = L\). It is important to note that the dimensionally reduced effective \((1 + 1)\)-dimensional model has “Lorentz” invariance; integrating out the \(L_y\)-modes does not destroy the proportionality between the imaginary time and the \(L_x\) directions. There is, therefore, one and only one correlation length \(\xi\). The result for \(\xi\) is

\[
\xi = \sqrt{32e^{\pi/2}}(2\pi C) \left(\frac{\hbar c}{2\pi \rho_s \hbar c}\right) \exp\left(\frac{2\pi \rho_s L}{\hbar c}\right) \left[1 - A \left(\frac{\hbar c}{2\pi \rho_s L}\right) + O\left(\frac{\hbar c}{2\pi \rho_s L}\right)^2\right].
\]

From strong coupling simulations, the quantity \(2\pi C\) was estimated in Ref. [3] to be between 0.01 and 0.013. This makes the overall numerical prefactor to be between 0.27 and 0.35. Since then an asymptotically exact expression has been derived [8], and the exact prefactor is known to be \(\epsilon/8 \approx 0.34\). In addition, the constant which was previously known to be only of order unity is determined to be \(A = 1/2\).

It is interesting to rewrite Eq. (5) in terms of the Josephson correlation length of the \((2 + 1)\)-dimensional \(O(3)\) non-linear \(\sigma\)-model \(\xi\), which is given by \(\xi = \left(\hbar c/\rho_s\right)\). This length separates the short distance critical behavior from the long distance Goldstone behavior. In terms of \(\xi\), the correlation length takes the simple finite-size scaling form:

\[
\xi = \frac{\pi l}{2} \left(\frac{\xi}{2\pi}\right) e^{2\pi L/\xi} \left(1 - \frac{1}{2} \left(\frac{\xi}{2\pi L}\right) + O\left(\frac{\xi}{2\pi L}\right)^2\right),
\]

(6)

For spin-\(S\) square-lattice Heisenberg antiferromagnet, \(\xi\) is given by

\[
\xi = \left(\frac{2\sqrt{2}Z_{\rho_s}}{S\pi L}\right)^{1/2} a.
\]

(7)

Because of “Lorentz” invariance, the spin gap, \(\Delta\), is simply \(\Delta = \hbar c/\xi\). Note again that the spin wave velocity does not renormalize and this relation does not have any corrections (cf. below). Specializing to \(S = 1/2\), we get

\[
(\Delta/a)^{1/2} = 0.490 e^{0.682(L/a)}\left[1 - 0.734(a/L)\right],
\]

(8)

\[
(\Delta/J)^{1/2} = 3.347 e^{-0.682(L/a)}\left[1 - 0.734(a/L)\right]^{-1}.
\]

(9)

The field theory analysis presumes that a continuum theory is applicable in both directions, and therefore the expressions in Eqs. (8) and (9) cannot be accurate for \((L/a) \sim 1\). Moreover, these expressions, obtained with a periodic boundary condition, are likely to be different from those obtained from other boundary conditions, such as the open boundary condition, especially when \((L/a) \sim 1\). Nonetheless, if we take \(L/a = 4\) corresponding to four-leg ladders, we get \((\Delta/J)^{1/2} = 0.268\), and \((\xi/a)^{1/2} = 6.23\). For \(L/a = 6\), we get \((\Delta/J)^{1/2} = 0.064\), and \((\xi/a)^{1/2} = 26.2\).

To compare, numerical results, with open boundary condition along \(L_y\), are available for \(L/a = 4\) and \(6\). According to Ref. [19], we have, for \(L/a = 4\), \((\Delta/J)^{1/2} = 0.190\), and \((\xi/a)^{1/2} = 5 - 6\). According to Ref. [20], we have, for \(L/a = 4\), \((\Delta/J)^{1/2} = 0.160\), and \((\xi/a)^{1/2} = 10.3\). From the same work, we have, for \(L/a = 6\), \((\Delta/J)^{1/2} = 0.055\). The value for the correlation length for \((L/a) = 6\) is not given explicitly. However, a simple extrapolation yields a value close to 30. From Ref. [21], we have, for \(L/a = 4\), \((\Delta/J)^{1/2} = 0.17\); for \(L/a = 6\), \((\Delta/J)^{1/2} = 0.05\).
Note that the gaps should be inversely proportional to the correlation lengths, where the proportionality constant does not renormalize due to “Lorentz” invariance. We require “Lorentz” invariance only in the $L_x$-$\tau$ plane. This has little to do with the fact that the width along $L_y$ is finite and equal to $L$. This proportionality is automatically satisfied for the analytical expressions given in this paper and should be a good check on the numerical work.

Based on the simple observation that at $T = 0$ the spin-$S$ square-lattice Heisenberg model of finite width can be mapped on to a $(2 + 1)$-dimensional $O(3)$ nonlinear $\sigma$-model with a finite dimension, I have provided a theory for crossover in spin ladders. Explicit analytical expressions for the correlation length and the spin gap were obtained by transcribing the results in Ref. [5]. The agreement with numerical calculations is very good considering the difference in the boundary conditions employed. The analytical expressions show precisely that the crossover to the two-dimensional limit is approached exponentially as the number of legs in the ladder system is increased. The extension of the present theory to anisotropic coupling and to finite temperature should be straightforward. I hope to return to these extensions in the future.

This work was conceived and carried out at the Aspen Center for Physics. It was supported by a grant from the National Science Foundation, Grant No. DMR-9531575.

[14] As shown in Ref. [3], a one-loop calculation of the fluctuations due to the finite size $L$ is sufficient to obtain an expression correct to two-loop order in the dimensionally reduced regime. The matching to strong coupling calculations, combined with a factor due to conversion of the regularization, then fixes the prefactor.
[15] In the lowest order spin wave theory, the quantities $Z_c$ and $Z_\chi$ are given by $Z_c = 1 + 0.158/2S + O(1/2S)^2$, and $Z_\chi = 1 - 0.552/2S + O(1/2S)^2$. For $S = 1/2$, accurate values are known for $Z_c$ and $Z_\chi$: $Z_c = 1.18, Z_\chi = 0.52$ (R. R. P. Singh, Phys. Rev. B 39, 9760 (1989); R. R. P. Singh and D. Huse, Phys. Rev. B 40, 7247 (1989)). These values are not very different from those obtained from the lowest order spin wave perturbation theory, which yields $Z_c = 1.15$, and $Z_\chi = 0.448$. The quantity $Z_{\rho_S}$, is given by $Z_{\rho_S}(S) = Z_S^2(S)Z_\chi(S)$. For $S = 1/2$, I shall use the more accurate values.
[16] For a bipartite lattice, the Marshall sign condition enforces zero total spin for even number of spins. If an additional spin is added, the total spin should be 1/2. This is true even for the broken symmetry phase, although by appropriately superposing states (P. W. Anderson, Phys. Rev. 86, 694 (1952)) a direction for the staggered order parameter can be chosen, and the doublet nature for odd number of spins is irrelevant. However, once $L_y$ is finite, the symmetry is restored, and the odd-even alternation must be allowed. The way to achieve this in a continuum theory is to recognize that the topological term is always present, even though its effect in the broken symmetry state can be ignored.
[17] In contrast to correlation length, the staggered susceptibility cannot be so simply obtained from Ref. [4]. For this we need equal time correlation function of the effective $(1 + 1)$-dimensional. From Ref. [3], we can read off trivially only the $q = \pi/a, \omega = 0$, susceptibility.
