Abstract

We have investigated the nature of flare emission from Sgr A* during multi-wavelength observations of this source that took place in 2004, 2005, and 2006. We present evidence for dimming of submillimeter and radio flux during the peak of near-IR flares. This suggests that the variability of Sgr A* across its wavelength spectrum is phenomenologically related. The model explaining this new behavior of flare activity could be consistent with adiabatically cooling plasma blobs that are expanding but also partially eclipsing the background quiescent emission from Sgr A*. When a flare is launched, the plasma blob is most compact and is brightest in the optically thin regime whereas the emission in radio/submillimeter wavelengths has a higher opacity. Absorption in the observed light curve of Sgr A* at radio/submillimeter flux is due to the combined effects of lower brightness temperature of plasma blobs with respect to the quiescent brightness temperature and high opacity of plasma blobs. This implies that plasma blobs are mainly placed in the magnetosphere of a disk-like flow or further out in the flow. The depth of the absorption being larger in submillimeter than in radio wavelengths implies that the intrinsic size of the quiescent emission increases with increasing wavelength which is consistent with previous size measurements of Sgr A*. Lastly, we believe that occultation of the quiescent emission of Sgr A* at radio/submillimeter by IR flares can be used as a powerful tool to identify flare activity at its earliest phase of its evolution.

1. INTRODUCTION

Observations of stellar orbits in the proximity of the enigmatic radio source Sgr A* located at the very dynamical center of our galaxy have established that it is a $4 \times 10^6 M_\odot$ black hole (Reid & Brunthaler 2004; Ghez et al. 2008; Gillessen et al. 2009). The emission from Sgr A* consists of quasi-steady and variable components (e.g., Hornstein et al. 2007; Dodds-Eden et al. 2010; Yusef-Zadeh et al. 2010). The variable component is now detected in almost all wavelength bands and is used to estimate the physical quantities of the gas flow, the radiation mechanism in different wavelength bands, and the scale lengths at which variable emission operates. One of the puzzling aspect of the flaring activity of Sgr A* is the physical nature of the variable emission in different wavelengths and how its spectrum evolves with time. Furthermore, it is not clear whether flares are deeply embedded in the accretion disk of Sgr A* or are physically distinct from the region where the bulk of the emission arises (Yusef-Zadeh et al. 2006a, 2008, 2009; Marrone et al. 2008; Eckart et al. 2008; Trap et al. 2010).

Flare emission at near-IR (IR) wavelengths is due to optically thin synchrotron emission and the submillimeter frequency is considered to be the dividing line between optically thin emission at high frequencies (near-IR) and optically thick emission at lower frequencies (submillimeter/radio). To examine the possibility that there is a causal association between radio/submillimeter variability and IR flaring activity, we studied in detail the light curves of flare emission from optically thick and thin plasma where there was sufficient overlap between IR/X-ray and submillimeter/radio wavelengths. We searched for signatures of optical depth effect against the background quiescent emission at the earliest phase of the evolution of flares.

2. DATA REDUCTION AND RESULTS

The primary purpose of our archival search was to find simultaneous observations of Sgr A* at submillimeter, radio, and IR wavelengths. We found three experiments that had overlaps between these wavelengths bands. Almost all the data presented here have already been published previously.

One multi-wavelength observing campaign was carried out on 2006 July 17 during which there was wavelength coverage between the Keck, Chandra, the Caltech Submillimeter Observatory (CSO), the Submillimeter Array (SMA), and the Very Large Array (VLA) of the National Radio Astronomy Observatory (NRAO; Hornstein et al. 2007; Marrone et al. 2008; Yusef-Zadeh et al. 2008). The CSO data are reanalyzed with a higher time sampling and the VLA data are recalibrated. The light curves presented at 7 and 13 mm have selected data corresponding to uv spacings greater than 100 kλ.

The second multi-wavelength observations took place on 2005 July 31 employing the CSO, the SMA, the Keck II, and Very Large Telescopes (VLTs). The time coverage on this day was excellent as there was a total of 10 continuous hours of observations with the Keck II and VLT telescopes at IR wavelengths (Hornstein et al. 2007; Marrone et al. 2008; Meyer et al. 2008). We searched for archival radio data from the VLA and found 7 mm (43 GHz) and 13 mm (12 GHz) data taken for a temporal coverage of about 4 hr on 2005 July 31. These data were taken in the C configuration using fast switching technique and a phase calibrators (0173+331, 17444-31166) to take out rapid atmospheric fluctuations. The light curves presented here...
are self-calibrated in phase using data corresponding to uv spacings >50\kappa.

Lastly, the campaign that took place on 2004 September 4 made simultaneous observations with the Hubble Space Telescope (HST/NICMOS) and CSO. The submillimeter data are reanalyzed with a better time sampling (Yusef-Zadeh et al. 2006b). The NICMOS data include photometry from three filters—F160W, F187N, and F190N—which are centered at wavelengths of 1.6, 1.87, and 1.90\mu m. The aperture photometry measurements have been corrected to an absolute flux scale, including an extinction correction that assumes A_K = 3.3 mag for Sgr A*.

Three examples in which there is evidence for anti-correlation of optically thin and thick flare emission are presented. The first set of light curves show radio observations of flaring activity that took place on 2005 July 31. Meyer et al. (2008) presented a 600 minute light curve by combining Keck II and VLT data. Sgr A* was highly active during this period showing several IR flares. Figure 1(a) shows IR and radio light curves. The bottom panels show individual 7 mm and 13 mm light curves in two different colors. Radio measurements indicate a remarkable trend that the emission is higher when there is a low-level flaring activity and is lower when there is a strong IR flare. This trend is best noted at times less than 5 hr UT and greater than 6 hr UT. The flux changes by about 150 and 100 mJy at 7 and 13 mm wavelengths, respectively. A more detailed view of flaring activity between 5.5 hr and 7.5 hr UT is shown in Figure 1(b). The light curves at 2.2 \mu m, 7 and 13 mm are presented with sampling time of 60 s, 30 s, and 30 s, respectively. The anti-correlation is evident clearly, first by the rise and fall of IR and radio activity during 5.5 hr and 7.5 hr UT. A more detailed examination of the radio emission anti-correlating with two of the strongest IR flares can best be viewed near 6 hr UT. Radio flux rises between the two peaks of flare emission at 5.8 hr and 6.2 hr UT. The fast fluctuations in the flux of Sgr A* at radio wavelengths appear to track the variation of flux at IR wavelengths. To clarify this relationship better, radio flux of Sgr A* is reversed before the change in radio flux is presented in Figure 1(c). The “correlation” of radio and IR flux is shown in remarkable clarity, given that the quiescent flux and the net variable flux are different at 7 and 13 mm wavelengths. The apparent discrepancy between 7 mm and 2.2 \mu m variation near 7.1 hr UT may be due to poor time sampling ~3 minutes of Keck data and a sudden change of observations from VLT to Keck which starts around 6.8 hr UT. The anti-correlation between near-IR and 1.3 mm data (Marrone et al. 2008) was not as clear as that of radio and near-IR data but 1.3 mm data could suffer from poor sampling and complication from time delayed emission. To examine the anti-correlation statistically, Figures 2(a) and (b) show the cross-correlation of the IR data with 7 mm and the merged 7 and 13 mm data, respectively. The cross-correlation analysis uses the ZDC function algorithm (Alexander 1997). A minimum in the likelihood value is identified at a zero time lag, strengthening the anti-correlation of IR and radio data.

The second evidence for dimming of optically thick light comes from observations made in 2006 July 17 (Marrone et al. 2008; Yusef-Zadeh et al. 2008). The authors showed evidence of a time delay between the peaks of IR/X-ray emission with respect to radio/submillimeter emission. Figure 3(a) shows simultaneous light curves of Sgr A* at X-rays between 2 and 8 keV, IR K’ band (Hornstein et al. 2007), 850 \mu m, 1.3 mm, and 7 mm. In these observations, as noted in the top panel of Figure 3(a), the second half of the X-ray flare was observed with Keck and showed evidence of flaring at IR wavelengths. This figure shows a dip in the flux of millimeter and submillimeter emission, during which an X-ray flare is detected. A close-up view during the peak emission at X-rays between 5:30 and 8 hr UT is shown in Figure 3(b). The light curves at 1.3 mm and 850 \mu m track each other well. However, we note that the 7 mm light curve seems to be somewhat shifted in time by with respect to the 1.3 mm light curve. The poor sampling of 1.3 mm data between 6 and 7 hr UT makes the comparison difficult. The largest drop in the 1.3 mm flux is noted at 6.7 hr UT. The average dimming at 850 \mu m, 1.3 mm, and 7 mm ranges between 0.5–1 Jy, 0.5 Jy, and 200–300 mJy, respectively. The 13 mm data also showed a very similar light curve to that of 7 mm with a flux variation of about 100–150 mJy. Another study by Doods-Eden et al. (2010) has argued for a decrease in the submillimeter flux during a near-IR flare, though the evidence was not convincing.

Although we note a general trend in the anti-correlation of X-ray and optically thick emission, this anti-correlation should have been evident between IR and optically thick emission. This is because X-ray emission is processed IR emission and does not exactly track the flux of an IR flare. The duration of a typical X-ray flare is generally shorter than in IR wavelengths (Doods-Eden et al. 2009; Marrone et al. 2008). The 2.2 \mu m flare of Figure 3 indicates that the duration of flare is longer than that observed in X-rays by at least 30 minutes on the decaying side of the flare. Unfortunately, there is no IR data available at times earlier than 6:45 hr UT. Nevertheless, the rise of flux at 7 mm, 1.3 mm, and 850 \mu m between 6 hr and 6:45 hr UT is consistent with the decline in the IR flux. Using the anti-correlation between IR and radio flux, we expect that the IR flare should have started around 5 hr UT with a flare duration of about 2 hr. Another feature we note in Figure 3 is a possible trend that the dimming of light appears to end first at longer wavelengths. However, this needs to be confirmed as SMA data are not sampled well during the dip in the quiescent flux of Sgr A*.

Lastly, the light curves showing evidence of dimming at submillimeter wavelengths are also detected in an observing campaign that took place on 2004 September 4. The light curves presented in Figure 4(a) show emission at 850 \mu m and three IR wavelengths at 1.6, 1.87, and 1.90 \mu m. Two strong IR flares and one submillimeter flare are detected near 4.2 hr UT, 7.6 hr UT, and 7 hr UT, respectively (see also Figure 10 of Yusef-Zadeh et al. 2006b). A previous analysis of submillimeter data using long sampling time of 20 minutes in the construction of the light curve suggested the possibility that the submillimeter flare is the counterpart either to flare at 4.3 hr UT delayed by ~200 minutes with respect to the first IR flare or to the second IR flare at 7.6 with no time delay (Yusef-Zadeh et al. 2006b). However, the new analysis shows a new feature that had not been recognized before. The 850 \mu m light curve indicates a decrease in the quiescent flux of Sgr A* by ~500 mJy during which the second IR flare occurred. We also note a decrease in the submillimeter flux at the start of IR observations when there is a detection of a flare. Figure 4(b) shows detailed views of the light curves to demonstrate the brightening and dimming of IR and submillimeter flux during flaring activity near 7.6 hr UT, respectively. This figure provides another support for a general trend in the anti-correlation between IR flare emission and submillimeter flux of Sgr A*. Exceptions to this trend are two data points at 7.8 hr UT during which submillimeter flux is lower than the peak IR flux near 7.5 hr UT. Unfortunately, the data are not sampled well at these wavelengths. Another effect that may
complicate the analysis of absorption in light curves at radio and submillimeter wavelengths could be due to flaring events that are time delayed and are superimposed on an absorbing feature.

3. DISCUSSION

The infrared wavelength band is the most important part of the spectrum of flare emission from Sgr A*. This is because...
Figure 2. (a) Left: the cross-correlation of IR and 7 mm light curves is shown in the bottom panel. (b) Right: similar to (a) except that radio data has merged the 7 and 13 mm data by adding a constant flux of 0.4 Jy to the 13 mm data.

(A color version of this figure is available in the online journal.)

Figure 3. (a) Left: the light curves of Sgr A* are shown in five different wavelengths. The X-ray (2–8 keV), IR, submillimeter (850 μm), 1.3 mm, and 7 mm data are binned every 207 s, 148 s, 120 s, 250 s, and 250 s, respectively (Hornstein et al. 2007; Marrone et al. 2008; Yusef-Zadeh et al. 2008). (b) Right: the same as (a) except that a close-up view of the light curves including an IR data at $L'$ band.

(A color version of this figure is available in the online journal.)
the flare is first launched in IR wavelengths followed by radio and submillimeter emission being delayed with respect to the peak in IR emission. In this model, flaring at a given frequency is produced through the adiabatic expansion of an initially optically thick blob of synchrotron-emitting relativistic electrons (van der Laan 1966). The expanding hot plasma model of Sgr A* flares has explained the nature of time delay of flare emission in the optically thick regime. However, the relationship between IR and radio/submillimeter flare emission has not been well established. Recent work has suggested that the optically thin component of flare emission is unrelated to the evolution of optically thick emission and that IR and radio/submillimeter flares emission operate independent of each other (e.g., Sabha et al. 2010). The light curves presented here demonstrate the dimming of the quiescent flux of Sgr A* at radio/submillimeter wavelengths while IR flares are observed.

The new measurements show that the observed flares in different frequencies operate under the same physical mechanism.

A likely scenario for the drop in flux seen at radio and submillimeter frequencies during IR flaring is that the electron population responsible for the flaring is optically thick at lower frequencies, partially obscures the submillimeter–radio emission from the accretion flow, and has a lower brightness temperature. To explore this picture, we construct a simple two-component model. The first component is a homogeneous, foreground, synchrotron emission region responsible for the IR flare. We characterize this by an $E^{-2}$ electron energy spectrum of relativistic electrons, a magnetic field strength $B$, and radius $R$. This component is responsible for the IR flare and also for producing the dips in the emission from Sgr A*. The second, background, component is responsible for the quiescent flux from Sgr A* in the radio and submillimeter is also homogeneous and is parameterized by its flux density $S_{q\nu}$ and radius $R_{q\nu}$, both of which are frequency-dependent. For simplicity, we assume that the two components are concentric, so that the fraction of the quiescent background source covered by the flaring component is $f = (R/R_{q\nu})^2$ when $R < R_{q\nu}$ and $f = 1$ otherwise.

The net flux received from Sgr A* in this simple model consists of contributions from the flaring region, and the obscured and unobscured fractions $f$ and $1 - f$ of the quiescent source:

$$S_{\nu} = \Omega J_{\nu} (1 - \exp(-\tau_{\nu})) + (1 - f) S_{q\nu} + f S_{q\nu} \exp(-\tau_{\nu})$$

(1)

$$S_{\nu} = S_{q\nu} + (\Omega J_{\nu} - f S_{q\nu})(1 - \exp(-\tau_{\nu}))$$

(2)

where the flare region has source function $J_{\nu}$, optical depth $\tau_{\nu}$, and subtends solid angle $\Omega = \pi R^2 / d^2$ at Earth, where $d = 8$ kpc is our adopted distance to the Galactic Center.

The synchrotron source function for an electron number density spectrum $n(E) \propto E^{-2}$ is

$$J_{\nu} = 0.646 \frac{\nu^2}{c^2} E_{\nu},$$

(3)

where

$$E_{\nu} = \left( \frac{4\pi m_e c^2 \nu}{3e B} \right)^{1/2} m_e c^2$$

(4)
is the typical energy of the electrons responsible for synchrotron emission at frequency $\nu$, and the other symbols have their usual meaning (e.g., Rybicki & Lightman 1986). We write the optical depth as $\tau_\nu = \kappa_\nu R$, where the synchrotron absorption coefficient is

$$\kappa_\nu = \frac{2}{9} \frac{e^3 B}{m_e c^2} n(E_\nu) \ .$$

(5)

Note that we have implicitly set the electron pitch angle to 90° in Equations (4) and (5). Finally, we adopt a fixed ratio between the energy density of the electron population, i.e., $U_e = \int E_\nu n(E_\nu) dE$ and the energy density of the magnetic field, i.e., $U_B = B^2/8\pi$, so that

$$n(E) = \frac{B^2}{8\pi \phi E^2}$$

(6)

between energies $E_1$ and $E_2$, where $\phi = (U_B/U_e) \ln(E_2/E_1)$.

The flux in the infrared is dominated by optically thin flare emission, and Equation (2) reduces to

$$\phi = \frac{E_\nu}{\nu} \Delta S_\nu$$

(7)

This allows us to use Equations (3)–(6) to compute the flare region’s magnetic field strength, optical depth, and source-function flux:

$$B = 38 (\phi_3 S_{10})^{2/7} R_{12}^{-6/7} G ,$$

(8)

$$\tau_\nu = 0.114 (\phi_3)^{-1/7} S_{10}^{8/7} R_{12}^{-17/7} v_{350}^{-3} ,$$

(9)

$$\phi = 1.7 (\phi_3 S_{10})^{-1/7} R_{12}^{17/7} v_{350}^{5/2} Jy ,$$

(10)

where we have scaled the results using $R_{12} = R/10^{12}$ cm, $\phi_3 = \phi/3$, $S_{10} = S/10$ mJy at 2.2 $\mu$m, and $v_{350} = \nu/350$ GHz. The weak dependence on the equipartition factor $\phi$ means that our results are insensitive to the ratio of the energy densities in the magnetic field and electron population.

Having determined the properties of the flare source region, we can compute its obscuring effect on the radio–submillimeter quiescent emission using Equation (2). By way of illustration we adopt $\phi = 3$, 10 mJy flux of at 2.2 $\mu$m, and quiescent fluxes $S_{350} = 3.0$ and 1.8 Jy at $\nu = 350$ and 43 GHz, respectively. At each frequency, for a given choice of quiescent source radius $R_{qv}$ we compute the flare region radius $R$ that would produce a specified drop in the total flux. The results are plotted in Figure 5 for flare-induced drops of 0.05, 0.1, and 0.2 Jy at 350 GHz (850 $\mu$m) and 43 GHz (7 mm).

At 350 GHz, absorption of $\sim 0.1$ Jy during an IR flare implies that both $R$ and $R_{qv}$ $\approx 10^{12}$ cm. The latter is consistent with the size of Sgr A* inferred from VLBI measurements at 230 GHz, which found a major axis FWHM $\sim 37$ $\mu$m (Doeleman et al. 2008) and in conjunction with lower frequency measurements (Bower et al. 2006) infer a $\nu^{-1.4\pm0.07}$ wavelength dependence, implying a major axis FWHM of $\sim 20$ $\mu$m at 350 GHz, equivalent to $2.4 \times 10^{13}$ cm. While choices of smaller $R$ in principle produce similar absorption levels, the magnetic field strength scales as $R^{-6/7}$ and exceeds 100 G for $R \lesssim 3 \times 10^{11}$ cm.

The 43 GHz curves in Figure 5 imply that values of $R$ much below $10^{12}$ cm require unrealistically small size for Sgr A* at 43 GHz. The radius of a flare $R \approx 10^{12}$ cm, on the other hand, implies that $R_{qv} \approx 5 \times 10^{12}$ cm at 43 GHz. While this is several times smaller than the measured semimajor axis, $\sim 2 \times 10^{13}$ cm, the semiminor axis is not yet determined and may be a few times less, so this discrepancy is not as large as may first appear. The cutoff in flare radius occurs because the brightness temperature of the flare emission scales as $B^{-1/2} \propto R^{3/7}$ and becomes comparable to that of the quiescent emission it is obscuring.

This simple model shows that occultation of Sgr A* by an IR flare source can produce noticeable dips in the flux from Sgr A* at radio and submillimeter frequencies. The major uncertainties are the electron spectral index, which is used to infer the optical depth at radio and submillimeter from the IR flux density, and the requirement that the IR flare region must overlie the radio emission. Note however that for a given IR flux density, a steeper electron spectrum implies greater optical depth at low frequencies. This latter would more naturally occur if the flare emission occurred in a magnetosphere of a disk-like flow or further out in the flow. One would expect that the geometry would not be favorable all of the time.

A recent model has considered time-dependent model of flare emission from Sgr A* (Dodds-Eden et al. 2010). They argue that flares are generated from the dissipation of the magnetic field due to the reconnection of the field in the accretion disk (see also Yuan et al. 2009). This model predicts a dimming of flux at submillimeter flux. Although their picture is quite consistent with some of the light curves presented here, more detailed observations are required to distinguish between these two models. In other words, the question is whether the occultation is due to an absorbing blob of hot plasma against a background quiescent flux of Sgr A* or due to a decrease in the flux as a consequence of the dissipation of the magnetic field due to reconnection of magnetic field lines. Future detailed modeling and observations with long time coverage should be able to address the difference between these two models.

This work is partially supported by the grant AST-0807400 from the NSF. We are grateful to D. Marrone, S. Hornstein, and F. Baganoff for providing us with their data.
