QUADRATIC POLYNOMIALS AND COMBINATORICS OF THE PRINCIPAL NEST

RODRIGO A. PÉREZ

Abstract. The definition of principal nest is supplemented with a system of frames that make possible the classification of combinatorial types for every level of the nest. As a consequence, we give necessary and sufficient conditions for the admissibility of a type and prove that given a sequence of non-renormalizable finite admissible types, there is a quadratic polynomial whose nest realizes the sequence.

1. Introduction

We will study the combinatorial behavior of the dynamics for quadratic polynomials with (non-periodic) recurrent critical orbit; these are the maps that have a well defined principal nest.

In [L2], M. Lyubich developed the principal nest as a tool to provide some examples of infinitely renormalizable parameters at which the Mandelbrot set is locally connected. The nest consists of a subsequence of central puzzle pieces, each determined by the first return of the critical orbit to the preceding nest piece.

As described in Section 2, the principal nest may include non-central pieces at some levels. Each piece \( V \) of the nest has a first return map onto the central piece of previous level that contains \( V \).

When the polynomial is real, the lateral pieces of the nest can only be located to the left or right of the central piece. This information, together with the sign of the derivative of the first return maps, is enough to provide a complete classification of real nest types (see [L1]). However, in the complex case, lateral pieces may “hang” from different branches of the Julia set. We exploit this underlying structure to construct a frame system that encodes the configuration of the nest. This allows us to describe the possible itineraries of the critical orbit as it visits different levels.

Our main classification result is the following:

Theorem: Any infinite sequence of finite, weak combinatorial types is realized in the quadratic family, as long as the types satisfy the admissibility condition at every level. The set of parameters that display this sequence of types can be described as the residual intersection in an infinite family of sequences of nested parapieces.

We illustrate the applicability of frames with a description of maximal hyperbolic components of the Mandelbrot set, and with the construction of complex analogues of the rotation-like maps of [BKP]. Further applications, including a classification of complex quadratic Fibonacci maps, are contained in [P].

1.1. Background and organization. The concept of a puzzle partition was introduced in [BH1] and [BH2] to study the topology of cubic Julia sets as a function of the critical points. In the late 80’s, J.-C. Yoccoz implemented the puzzle in the setting of quadratic polynomials, in order to prove the MLC conjecture for the case of finitely renormalizable parameters (see [H]). The idea of the puzzle construction is to show that the pieces around the critical point become arbitrarily small, thus providing a system of neighborhoods that satisfy the local connectivity condition. For Yoccoz’s puzzle, this is done by showing that the moduli of annuli between consecutive pieces generate a divergent series. In the case of the principal nest, the moduli between consecutive nest pieces

Research supported by an NSF Postdoctoral Fellowship in the Mathematical Sciences, grant DMS-0202519.
increase in an essentially linear fashion. The principal nest technique underlies Lyubich’s proofs of the Feigenbaum-Collet-Tresser conjecture and the theorem on the measure-theoretic attractor.

In order to fix notation, we introduce basic notions of Complex Dynamics in Section 2. In particular, we describe the puzzle construction of Yoccoz and the principal nest following Lyubich.

In Section 3 we define the frame associated to a nest. The construction requires particular care at the initial steps in order to ensure that nest levels and frame levels go hand by hand. Then we specify a labeling of frame cells and produce a language to describe admissible combinatorial types. Our main result (Theorem 3.6 and Corollary 3.7) is stated and proved there.

Section 4 illustrates the use of our construction with two examples; a classification of maximal hyperbolic components of the Mandelbrot set according to the combinatorial type of their nests, and an extension of the family of rotation-like maps described in [BKP].

A brief summary of holomorphic motions is included in an appendix.

1.2. Acknowledgments. This work contains results from my dissertation. Many thanks are due to my advisors John Milnor and Mikhail Lyubich for their generous support during the preparation of the Thesis. I would also like to thank John Smillie for suggestions to improve the presentation. Finally, some of the pictures were created with the PC program mandel.exe by Wolf Jung [J].

2. Basics in Complex Dynamics

2.1. Basic notions. In order to fix notation, let us start by defining the basic notions of complex dynamics that will be used; we refer the reader to [DH1] and [M 1] for details on this introductory material.

We focus attention on the quadratic family \( Q := \{ f_c : z \mapsto z^2 + c \mid c \in \mathbb{C} \} \). For every \( c \), the compact sets \( K_c := \{ z \mid \text{the sequence } \{ f_c^n(z) \text{ is bounded} \} \) and \( J_c := \partial K_c \) are called the filled Julia set and Julia set respectively. Depending on whether the orbit of the critical point 0 is bounded or not, \( J_c \) and \( K_c \) are connected or totally disconnected. The Mandelbrot set is defined as \( M := \{ c \mid c \in K_c \} \); that is, the set of parameters with bounded critical orbit; see Figure II.

A component of \( \text{int} M \) that contains a superattracting parameter will be called a hyperbolic component\(^1\). The boundary of a hyperbolic component can either be real analytic, or fail to be so at one cusp point. The later kind are called primitive components. In particular, the hyperbolic component \( \partial M \) associated to \( z \mapsto z^2 \) is bounded by a cardioid known as the main cardioid.

\( M \) contains infinitely many small homeomorphic copies of itself, accumulating densely around \( \partial M \). In fact, every hyperbolic component \( H \) other than the main one is the base of one such small copy \( M' \). \( H \) is called prime if it is not contained in any other small copy. To simplify later statements, prime components are further subdivided in immediate (non-primitive components that share a boundary point with \( \partial \)) and maximal (primitive components away from \( \partial \)).

2.2. External rays, wakes and limbs. Since \( f^{-1}_c(\infty) = \{ \infty \} \), the point \( \infty \) is a fixed critical point and a result of Böttcher yields a change of coordinates that conjugates \( f_c \) to \( z \mapsto z^2 \) in a neighborhood of \( \infty \). With the requirement that the derivative at \( \infty \) is 1, this conjugating map is denoted \( \varphi_c : N_c \longrightarrow \mathbb{C} \setminus \mathbb{D}_R \), where \( \mathbb{D}_R \) is the disk of radius \( R \geq 1 \) and \( N_c \) is the maximal domain of unimodality for \( \varphi_c \). It can be shown that \( N_c = \mathbb{C} \setminus K_c \) and \( R = 1 \) whenever \( c \in M \). Otherwise, \( N_c \) is the exterior of a figure 8 curve that is real analytic and symmetric with respect to 0. In this case, \( R > 1 \) and \( K_c \) is contained in the two bounded regions determined by the 8 curve.

Consider the system of radial lines and concentric circles in \( \mathbb{C} \setminus \mathbb{D}_R \) that characterizes polar coordinates. The pull back of these curves by \( \varphi_c \) creates a collection of external rays \( r \) \(( \theta \in [0, 1) \) and equipotential curves \( e_s \) (here \( s \in (R, \infty) \) is called the radius of \( e_s \)) on \( N_c \). These form

\(^1\)Though, of course, it is conjectured that all interior components are hyperbolic.
two orthogonal foliations that behave nicely under dynamics: $f_c(r_\theta) = r_{2\theta}$, $f_c(e_s) = e_{(s^2)}$. When $c \in M$, we say that a ray $r_\theta$ lands at $z \in J_c$ if $z$ is the only point of accumulation of $r_\theta$ on $J_c$.

A similar coordinate system exists around the Mandelbrot set. For $c \not\in M$, we define the map

$$\Phi_M(c) := \varphi_c(c).$$

In [DH1] it is shown that $\Phi_M : \mathbb{C} \setminus M \rightarrow \mathbb{C} \setminus \mathbb{D}$ is a conformal homeomorphism tangent to the identity at $\infty$. This yields connectivity of $M$ and allows us to define parametric external rays and parametric equipotentials as in the dynamical case. Since there is little risk of confusion, we will use the same notation $(r_\theta, e_s)$ to denote these curves and say that a parametric ray lands at a point $c \in \partial M$ if $c$ is the only point of accumulation of the ray on $M$.

For the rest of this work, all rays considered, whether in dynamical or parameter plane, will have rational angles. These are enough to work out our combinatorial constructions and satisfy rather neat properties.

**Proposition 2.1.** ([M1], ch.18) Both in the parametric and the dynamical situations, if $\theta \in \mathbb{Q}$ the external ray $r_\theta$ lands. In the dynamical case, the landing point is (pre-)periodic with the period and preperiod determined by the binary expansion of $\theta$. A point in $J_c$ (respectively $\partial M$) can be the landing point of at most, a finite number of rays (respectively parametric rays). If this number is larger than 1, each component of the plane split by the landing rays will intersect $J_c$ (respectively $\partial M$).

Unless $c = \frac{1}{4}$, $f_c$ has two distinct fixed points. If $c \in M$, these can be distinguished since one of them is always the landing point of the ray $r_0$. We call this fixed point $\beta$. The second fixed point is called $\alpha$ and can be attracting, indifferent or repelling, depending on whether the parameter $c$ belongs to $\varnothing$, $\partial \varnothing$, or $\mathbb{C} \setminus \varnothing$. The map $\psi_0 : \varnothing \rightarrow \mathbb{D}$ given by $c \mapsto f_c'(\alpha_c)$ is the Riemann map of $\varnothing$ normalized by $\psi_0(0) = 0$ and $\psi_0'(0) > 0$. Since the cardioid is a real analytic curve except at $\frac{1}{4}$, $\psi_0$ extends to $\varnothing$.

The fixed point $\alpha$ is parabolic exactly at parameters $c_\eta \in \partial \varnothing$ of the form $c_\eta = \psi_0^{-1}(e^{2\pi i \eta})$ where $\eta \in \mathbb{Q} \cap [0,1)$. If $\eta \neq 0$, $c_\eta$ is the landing point of two parametric rays $r_{t^-}(\eta)$ and $r_{t^+}(\eta)$.

**Definition:** The closure of the component of $\mathbb{C} \setminus (r_{t^-}(\eta) \cup c_\eta \cup r_{t^+}(\eta))$ that does not contain $\varnothing$ is called the $\eta$-wake of $M$ and is denoted $W_\eta$. The $\eta$-limb is defined as $L_\eta = M \cap W_\eta$. 

3
**Definition:** Say that η = \( \frac{p}{q} \), written in lowest terms. Then \( P(\frac{p}{q}) \) will denote the unique set of angles whose behavior under doubling is a cyclic permutation with combinatorial rotation number \( \frac{p}{q} \).

If \( P(\frac{p}{q}) = \{t_1, \ldots, t_q\} \), then for any parameter \( c \in L_{p/q} \) the corresponding point \( \alpha \) splits \( K_c \) in \( q \) parts, separated by the \( q \) rays \( \{r_{t_1}, \ldots, r_{t_q}\} \) landing at \( \alpha \). The two rays whose angles span the shortest arc separate the critical point 0 from the critical value \( c \); these two angles turn out to be \( t^-(\frac{p}{q}) \) and \( t^+ (\frac{p}{q}) \).

2.3. **Yoccoz puzzles.** The Yoccoz puzzle is well defined for parameters \( c \in L_{p/q} \) for any any \( \frac{p}{q} \in \mathbb{Q} \cap [0,1) \) with \( (p,q) = 1 \). If 0 is not a preimage of \( \alpha \), the puzzle is defined at infinitely many depths and we will restrict attention to these parameters. Since we describe properties of a general parameter, we will omit the subscript and write \( f \) instead of \( f_c \), \( K \) instead of \( K_c \) and so on.

Let us fix the neighborhood \( U \) of \( K \) bounded by the equipotential of radius 2. The rays that land at \( \alpha \) determine a partition of \( U \) into \( \{r_{t_1}, \ldots, r_{t_q}\} \) in \( q \) connected components. We will call the closures \( Y_0^{(0)}, Y_1^{(0)}, \ldots, Y_{q-1}^{(0)} \) of these components, puzzle pieces of depth 0. At this stage the labeling is chosen so that \( 0 \in Y_0^{(0)} \) and \( f(K \cap Y_j^{(0)}) = K \cap Y_{j+1}^{(0)} \); where the subindices are understood as residues modulo \( q \). In particular, \( Y_1^{(0)} \) contains the critical value \( c \) and the angles of its bounding rays are \( t^-(\frac{p}{q}), t^+ (\frac{p}{q}) \).

The puzzle pieces \( Y_j^{(n)} \) of higher depths are recursively defined as the closures of every connected component in \( f^{\circ(-n)}(\bigcup \text{Int} Y_j^{(0)}) \); see Figure 2. At each depth \( n \), there is a unique piece which contains the critical point and we will always choose the indices so that \( 0 \in Y_0^{(n)} \).

We will denote by \( P_n \) the collection of pieces of level \( n \). The resulting family \( \mathcal{Y}_c := \{P_0, P_1, \ldots\} \) of puzzle pieces of all depths, has the following two properties:

**P1** Any two puzzle pieces either are nested (with the piece of higher depth contained in the piece of lower depth), or have disjoint interiors.

**P2** The image of any piece \( Y_i^{(n)} (n \geq 1) \) is a piece \( Y_i^{(n-1)} \) of the previous depth \( n - 1 \). The restricted map \( f: \text{Int} Y_i^{(n)} \rightarrow \text{Int} Y_i^{(n-1)} \) is a 2 to 1 branched covering or a conformal homeomorphism, depending on whether \( j = 0 \) or not.

These properties characterize \( \mathcal{Y}_c \) as a Markov family, endowing the puzzle partition with dynamical meaning.

Note that the collection of ray angles at depth \( n \) consists of all \( n \)-preimages of \( \{r_{t_1}, \ldots, r_{t_q}\} \) under angle doubling. The union of all pieces of depth \( n \) is the region enclosed by the equipotential \( e^{(2\pi n)} \). Note also that every piece \( Y \) of depth \( n \) is the \( n \)-th preimage of some piece of level 0. By further iteration, \( Y \) will map onto a region determined by the same rays as \( Y_0^{(0)} \) and a possibly larger equipotential. This provides a 1 to 1 correspondence between puzzle pieces and preimages of 0. The distinguished point inside each piece is called the center of the piece.

2.4. **Adjacency Graphs.** Given a set of puzzle pieces \( P \subseteq P_n \), we define the dual graph \( \Gamma(P) \) as a formal graph whose set of vertices is \( P \) and whose edges join pairs of pieces that share an arc of external ray. It is always possible to produce an isomorphic model of \( \Gamma(P) \) sitting in the plane, without intersecting edges and such that it respects the natural immersion of \( \Gamma(P) \) in the plane.

**Definition:** When \( P = P_n \), we call \( \Gamma_n := \Gamma(P_n) \) the puzzle graph of depth \( n \). In this context, the vertices corresponding to the central piece \( Y_0^{(n)} \) and the piece around the critical value \( f_c(0) \) are denoted \( \xi_n \) and \( \eta_n \), respectively.
Proposition 2.2. The puzzle graphs of a subgraph of $\Gamma$ sequences of the structure of quadratic Julia sets. The configuration of $\Gamma$ also respects order in the sense of $G_5$.

Proof of Proposition 2.2: Let $\Gamma$ be a graph isomorphic to a subgraph of $\Gamma$ when every path from $a$ to $\eta_n$ passes through $b$. We write $a >_{\xi_n} b$ when every path from $a$ to $\xi_n$ passes through $b$ or through its symmetric image with respect to the origin.

The following are natural consequences of the definitions; see Figure 2 for reference.

**Definition:** The vertices $\xi_n$ and $\eta_n$ determine two partial orders on the vertex set of $\Gamma$ as follows: If $a, b \in V(\Gamma)$, we write $a >_{\eta_n} b$ when every path from $a$ to $\eta_n$ passes through $b$. We write $a >_{\xi_n} b$ when every path from $a$ to $\xi_n$ passes through $b$ or through its symmetric image with respect to the origin.

The following are natural consequences of the definitions; see Figure 2 for reference.

**Proposition 2.2.** The puzzle graphs of $f$ satisfy:

**G1** $\Gamma_n$ has 2-fold central symmetry around $\xi_n$.

**G2** $\Gamma_0$ is a $q$-gon whenever $c \in L_{p/q}$. For $n \geq 1$, $\Gamma_n$ consists of $2^n$ $q$-gons linked at their vertices in a tree-like structure; i.e. the only cycles on this graph are the $q$-gons themselves.

**G3** For $n \geq 1$, removing $\xi_n$ and its edges splits $\Gamma_n$ into 2 disjoint (possibly disconnected) isomorphic graphs. Reattaching $\xi_n$ to each, and adding the corresponding edges defines the connected graphs $\text{Puzz}_n^-$ and $\text{Puzz}_n^+$ (here, $\eta_n \in \text{Puzz}_n^-$). Then $\Gamma_n = \text{Puzz}_n^- \cup \text{Puzz}_n^+$ and $\text{Puzz}_n^-, \text{Puzz}_n^+$ are isomorphic to $\Gamma_{n-1}$ with $\mp \eta_n$ playing the role of $\xi_{n-1}$ in $\text{Puzz}_n^\pm$.

**G4** For $n \geq 1$ there are two natural maps: $f^*: \Gamma_n \rightarrow \Gamma_{n-1}$ induced by $f$, and $\iota^*: \Gamma_n \rightarrow \Gamma_{n-1}$ induced by the inclusion among pieces of consecutive depths. $f^*$ is 2 to 1 except at $\xi_n$ and sends $\text{Puzz}_n^\pm$ onto $\Gamma_{n-1}$. In turn, $\iota^*$ collapses the outermost $q$-gons into vertices.

**G5** The map $f^*: (\Gamma_n, >_{\xi_n}) \rightarrow (\Gamma_{n-1}, >_{\eta_{n-1}})$ respects order. That is, if $a >_{\xi_n} b$ then $f^*(a) >_{\eta_{n-1}} f^*(b)$.

**Definition:** Let $\Gamma$ be a graph isomorphic to a subgraph of $\Gamma_n$ and $\Gamma'$ a graph isomorphic to a subgraph of $\Gamma_{n-1}$. A map $E: \Gamma \rightarrow \Gamma'$ that satisfies $[\text{G1}]$ and $[\text{G2}]$ will be called admissible if it also respects order in the sense of $[\text{G5}]$.

**Proof of Proposition 2.2:** Property $[\text{G1}]$ and the existence of $f^*$ and $\iota^*$ are immediate consequences of the structure of quadratic Julia sets. The configuration of $\Gamma_0$ is given by the rotation number around $\alpha$ and then the tree-like structure of $\Gamma_n$ ($n \geq 1$) follows from $[\text{G3}]$.

Consider a centrally symmetric simple curve $\gamma \subset Y_0^{(n)}$ connecting two opposite points of the equipotential curve $e_{(2^{n-1})}$ that bounds $Y_0^{(n)}$. Then $\gamma$ splits the simply connected region $\bigcup_{Y \in P_n} Y$ in 2 identical parts. Therefore, $\Gamma \setminus \xi_n$ is formed by 2 disjoint graphs justifying the existence of $\text{Puzz}_n^\pm$. However, $\partial Y_0^{(n)}$ may contain several segments of $e_{(2^{n-1})}$; so $\gamma$, and consequently $\text{Puzz}_n^\pm$...
are not uniquely determined. This ambiguity is not consequential; Lemmas 3.4 and 3.5 describe the proper method of handling it.

The fact that \( f \) maps the central piece to a non-central one containing the critical value legitimizes the selection of \( \text{Puzz}_n \) as the unique graph containing \( \eta_n \). By symmetry, every piece of \( P_n \) except the central one has a symmetric partner and they both map in a 1 to 1 fashion to the same piece of \( P_{n-1} \). The isomorphisms in \( G^3 \) follow.

If two pieces \( A, B \) of depth \( n \) share a boundary ray, their images will too. Moreover, letting \( A', B' \) be the pieces of depth \( n - 1 \) containing \( A \) and \( B \), it is clear that \( \partial A' \) and \( \partial B' \) must share the same ray as \( \partial A \) and \( \partial B \). This shows that \( f^* \) and \( \iota^* \) effectively preserve edges and are well defined graph maps. Clearly \( f^* \) is 2 to 1, so to complete the proof of \( G^4 \) we only need to justify the collapsing property of \( \iota^* \), and by Property \( G^3 \) it is sufficient to consider the case \( \iota^* : \Gamma_1 \rightarrow \Gamma_0 \). Now, the non-critical piece \( Y_j^{(0)} \) contains a unique piece \( Y_j \) of \( P_1 \). However, the critical piece \( Y_0^{(0)} \) contains a total of \( q \) different pieces of depth 1: a smaller central piece \( Y_0^{(1)} \) and \( q - 1 \) lateral pieces \( -Y_j \). The resulting graph, \( \Gamma_1 \), consists then of two \( q \)-gons joined at the vertex \( \xi_1 \). Under \( \iota^* \), one of these \( q \)-gons collapses on the critical vertex \( \xi_0 \).

To prove \( G^5 \) let us construct the tree \( \Gamma'_n \) with 2 to 1 central symmetry by collapsing every \( q \)-gon into a single vertex. The orders \( \succ \xi_n, \succ \eta_n \) in \( \Gamma'_n \) are induced by the orders in \( \Gamma_n \). Then the corresponding map \( f'' : (\Gamma'_n, \succ \xi_n) \rightarrow (\Gamma'_{n-1}, \succ \eta_n) \) is a 2 to 1 map on trees that takes each half of \( \Gamma'_n \) injectively into a sub-tree of \( \Gamma'_{n-1} \) and respects order. Since vertices in a cycle are not ordered, \( f^* \) respects order as well.

\[ \square \]

2.5. Parapuzzle. While the puzzle encodes the combinatorial behavior of the critical orbit for a specific map \( f_c \), the parapuzzle dissects the parameter plane into regions of parameters that share similar behaviors: In every wake of \( M \) we define a partition in pieces of increasing depths, with the property that all parameters inside a given parapiece share the same critical orbit pattern up to a specific depth.

Definition: Consider a wake \( W_{p/q} \) and let \( n \geq 0 \) be given. Call \( W^n \) the wake \( W_{p/q} \) truncated by the equipotential \( e_{(2^{2-n})} \) and consider the set of angles \( P_n(\xi_{\frac{p}{q}}) = \{ t \mid 2^{m} t \in P(\xi_{\frac{p}{q}}) \} \) (compare Subsection 2.2). The parapieces of \( W_{p/q} \) at depth \( n \) are the closures of the components of \( W^n \setminus \{ r \in P_n(\xi_{\frac{p}{q}}) \} \).

Note: Even though the critical value \( f_c(0) \) is simply \( c \), it will be convenient to write \( c \in \Delta \) when \( \Delta \) is a parapiece and \( f_c(0) \in V \) when \( V \) is a piece in the dynamical plane of \( f_c \). In general, we will use the notation \( \text{OBJ}(c) \) to refer to dynamically defined objects \( \text{OBJ} \) associated to a specific parameter \( c \).

Definition: When the boundary of a dynamical piece \( A \) is described by the same equipotential and ray angles as those of a parapiece \( B \), we denote this relation by \( \partial A \cong \partial B \).

Definition: Let \( c \in M \) be a parameter whose puzzle is defined up to depth \( n \). We denote by \( CV_n[c] \in P_n[c] \) the piece of depth \( n \) that contains the critical value: \( f_c(0) \in CV_n[c] \).

A consequence of Formula 2.4 is the well known fact that follows. For a proof of the main statement, refer to [DH2] or [R]. For a proof of the winding number property, refer to [D2] and Proposition 3.3 of [L3]; also, see the Appendix for the definition of holomorphic motions.

Proposition 2.3. Let \( \Delta \) be a parapiece of depth \( n \) in some wake \( W \). Then \( CV_n[c] \cap \Delta \) for every \( c \in \Delta \) so the family \( \{ c \mapsto CV_n[c] \mid c \in \Delta \} \) is well defined; it determines a holomorphic motion of the critical value pieces. The holomorphic motion has \( \{ c \mapsto f_c(0) \} \) as a section with winding number 1.
We can interpret the result on winding number as loosely saying that, as \( c \) goes once around \( \partial \Delta \), the critical value \( f_c(0) \) goes once around \( \partial CV_n \). However, this description is not entirely accurate since \( \partial CV_n[c] \) changes with \( c \).

Let us mention the following examples of combinatorial properties that depend on the behavior of the first \( n \) iterates of 0. The fact that these entities remain unchanged for \( c \in \Delta \) follows from Proposition 2.3 and will be useful in the next sections.

- The isomorphism type of \( \Gamma_n[c] \).
- The combinatorial boundary of every piece of depth \( \leq n \).
- The location within \( P_n[c] \) of the first \( n \) iterates of the critical orbit.

From the general results of [L3], we can say more about the geometric objects associated to the above examples.

**Proposition 2.4.** Each of the sets listed below moves holomorphically as \( c \) varies in \( \Delta \):

- The boundary of every piece of depth \( \leq n \).
- The first \( n \) iterates of the critical orbit.
- The collection of \( j \)-fold preimages of \( \alpha \) and \( \beta \) \((j \leq n)\).

### 2.6. Principal nest.

The principal nest is well defined for parameters \( c \) that belong neither to \( \overline{\Delta} \) nor to an immediate component. The first condition means that both fixed points are repelling (so the puzzle is defined), while the second condition characterizes those polynomials that do not admit an immediate renormalization as described below. We restrict further to parameters \( c \) such that the orbit of 0 is recurrent to ensure that the nest is infinite. These necessary conditions will justify themselves as we describe the nest.

In order to explain the construction of the principal nest, we need a more detailed description of the puzzle partition at depth 1 (use Figure 3 for reference). As a note of warning, the pieces of depth 1 will be renamed to reflect certain properties of \( P_1 \). That is, we will override the use of the symbols \( Y_j^{(1)} \).

The puzzle depth \( P_1 \) consists of \( 2q-1 \) pieces of which \( q-1 \) are the restriction to lower equipotential of the pieces \( Y_1^{(0)}, Y_2^{(0)}, \ldots, Y_{q-1}^{(0)} \). Such pieces cluster around \( \alpha \) and will be denoted \( Y_1, Y_2, \ldots, Y_{q-1} \).

The restriction of \( Y_0^{(0)} \) however, is further divided into the union of the critical piece \( Y_0^{(1)} \) and \( q-1 \) pieces \( Z_1, Z_2, \ldots, Z_{q-1} \) which are symmetric to the corresponding \( Y_j \) and cluster around \( -\alpha \). The indices are again determined by the rotation number of \( \alpha \) so that \( f(Z_j) \) is opposite to \( Y_j \) and consequently \( f(Z_j) = Y_0^{(1)} \).

Note that \( f^{\nu(q)}(0) \in Y_0^{(1)} \), so we face two possibilities. It may happen that \( f^{\nu(q)}(0) \in Y_0^{(1)} \) for all \( q \), in which case we can find *thickenings* of \( Y_0^{(1)} \) and \( Y_0^{(0)} \), that yield the immediate renormalization \( f^{\nu(q)} : Y_0^{(1)} \rightarrow Y_0^{(0)} \) described by Douady and Hubbard; or else, we can find the least \( k \) for which the orbit of 0 under \( f^{\nu(q)} \) escapes from \( Y_0^{(1)} \). We will assume that this is the case, so \( f^{\nu(q)}(0) \in Z_\nu \) for some \( \nu \) and we call \( kq \) the first escape time.

The initial nest piece \( V_0^0 \) is defined as the \((kq)\)-fold pull back of \( Z_\nu \) along the critical orbit; that is, the unique piece that satisfies \( 0 \in V_0^0 \) and \( f^{\nu(q)}(V_0^0) = Z_\nu \). In fact, \( V_0^0 \) can also be defined as the largest central piece that is compactly contained in \( Y_0^{(1)} \): Notice that \( Z_\nu \subseteq Y_0^{(0)} \) so \( V_0^0 \subseteq Y_0^{(1)} \); that is, \( \text{int } Y_0^{(1)} \) \( \setminus V_0^0 \) is a non-degenerate annulus.

The higher levels of the principal nest are defined inductively. Suppose that the pieces \( V_0^0, V_0^1, \ldots, V_0^n \) have been already constructed. If the critical orbit never returns to \( V_0^n \) then the nest is finite. Otherwise, there is a first return time \( \ell_n \) such that \( f^{\ell_n}(0) \in V_0^0 \); then we define \( V_0^{n+1} \) as the critical piece that maps to \( V_0^n \) under \( f^{\ell_n} \).
**Figure 3.** Puzzle $P_1(f_c)$ of depth 1, where $c = (0.35926...) + i(0.64251...)$. The center of the component of period 5 in $L_{1/4}$. The first escape is $f_c^{04}(0) \in Z_3$ and the pull back $V_0^0$ is shown in dotted lines. Note that $f_c^{05}(0) \in V_0^0$. This creates at once the piece $V_0^1 \in V_0^0$ around the central component of $\mathbb{C} \setminus J_c$ ($V_0^1$ is not shown).

**Proposition 2.5.** The principal nest $V_0^0 \supset V_0^1 \supset \ldots$ is a family of strictly nested pieces centered around 0.

**Proof:** $V_0^0$ is a piece of depth $kq$ (the first escape time). Since $V_0^1$ is a $f^{\ell_1}$-pull back of $V_0^0$, it is a piece of depth $kq + \ell_1$ and, in general, $V_0^n$ will be a piece of depth $kq + \ell_1 + \cdots + \ell_n$. Since all pieces contain 0, Property $\mathbf{P1}$ implies that $V_0^j \supset V_0^{j+1}$.

Recall that $V_0^0 \in V_0^{(1)}$; thus, the $f^{\ell_1}$-pull backs of these 2 pieces satisfy $V_0^1 \in X$ with $X$ a central piece of depth $1 + \ell_1$. Now, $0 \notin Z_\nu$, so $f^{\ell_1q}(0)$ requires further iteration to reach a central piece; i.e., $\ell_1 > kq$. By construction, $V_0^0$ is a central piece of depth 1 + $kq$, so Property $\mathbf{P1}$ implies $V_0^1 \in X \subset V_0^0$. An analogous argument yields the strict nesting property for the nest pieces of higher depth.

**Definition:** The principal annuli $V_0^{n-1} \setminus V_0^n$ will be denoted $A_n$.

It may happen that $\ell_{n+1} = \ell_n$; this means that not only does 0 return to $V_0^n$ under $f^{\ell_n}$, but even deeper to $V_0^{n+1}$ without further iteration. In this case we say that the return is central and we call a chain of consecutive central returns $\ell_n = \ell_{n+1} = \ldots = \ell_{n+s}$ a **cascade of central returns**. An infinite cascade means that the sequence $\{\ell_n\}$ is eventually constant, so $f^{\ell_n}(0) \in \bigcap_{j=n}^{\infty} V_0^j$. By definition, $f^{\ell_n} : V_0^{n+1} \rightarrow V_0^n$ is a renormalization of $f$; that is, a 2 to 1 branched cover of $V_0^n$ such that the orbit of the critical point is defined for all iterates.

The return to $V_0^n$, however, can be non-central. In fact, it is possible to have several returns to $V_0^n$ before the critical orbit hits $V_0^{n+1}$ for the first time. When a return is non-central, the description of the nest at that level is completed by the introduction of the **lateral** pieces $V_k^n \in V_0^{n-1} \setminus V_0^n$. Let $\mathcal{O} \subset K$ denote the critical orbit $\mathcal{O} = \{f^j(0)|j \geq 0\}$ and take a point $z \in \partial \mathcal{O} \cap V_0^{n-1}$ whose forward orbit returns to $V_0^{n-1}$. If we call $r_{n-1}(z)$ the first return time of $z$ back to $V_0^{n-1}$, we can define $V^n(z)$ as the unique puzzle piece that satisfies $z \in V^n(z)$ and $f^{r_{n-1}}(V^n(z)) = V_0^{n-1}$. 

In particular, it is clear that $V^n(0)$ is just the same as $V_0^n$ and that any 2 pieces created by this process are disjoint or equal.

**Definition:** The collection of all pieces $V^n(z)$ for $z \in \mathcal{O} \cap V_0^{n-1}$ that actually contain a point of $\mathcal{O}$ is denoted $\mathcal{V}^n$ and referred to as the level $n$ of the nest.

![Figure 4. Relation between consecutive nest levels. The curved arrow represents the first return map $f^{\circ n} : V_0^n \to V_0^{n-1}$ which is 2 to 1. The dotted arrows show a possible effect of this map on each nest piece of level $n+1$. Each $V_{j}^{n+1}$ may require a different number of additional iterates to return to this level and map onto $V_0^n$.](image)

Under the assumption that $c$ is recurrent, the principal nest will have infinitely many levels. Let us assume the parameter $c$ is not periodic. Then it is called **reluctantly recurrent** if for some central piece $V_0^n$ there are arbitrarily long sequences of univalent $f_c$-pull backs of $V_0^n$ along backward orbits in the postcritical set $\mathcal{O}$. Otherwise, $c$ is called **persistently recurrent**.

**Lemma 2.6.** (see [L1], [Ma]) If $f_c$ is persistently recurrent, $\mathcal{O}$ is a Cantor set and the action of $f_c|_{\mathcal{O}}$ is minimal. When $f_c$ is not renormalizable, $c$ is reluctantly recurrent if and only if some central piece $V_0^n$ has infinitely many 1 to 2 pull backs along backward orbits of $\mathcal{O}$.

**Observation:** In particular, if $c$ is non-renormalizable but every level of the principal nest has a finite number of pieces, then $f_c$ acts minimally on the postcritical set. In this situation, we can name the pieces $\mathcal{V}^n = \{V_0^n, V_1^n, \ldots, V_m^n\}$ in such a way that the first visit of the critical orbit to $V_i^n$ occurs before the first visit to $V_j^n$ whenever $i < j$. Obviously, the value of $r_{n-1}(z)$ is independent of $z \in V_k^n$; thus we will denote it $r_{n,k}$.

**Definition:** For finite $\mathcal{V}^n$ we define the map:

$$g_n : \bigcup_{V_k^n} V_k^n \to V_0^{n-1},$$

given on each $V_k^n$ by $g_n|_{V_k^n} \equiv f^{\circ r_{n,k}}$. 

9
The map \( g_n \) satisfies the properties of a generalized quadratic-like (\( gql \)) map, i.e.:

- \( |V^n| < \infty \).
- \( \bigcup_{V^n} V^n_k \cap V^n_0 \) and all the pieces of \( V^n \) are pairwise disjoint.
- \( g_{n|V^n_k} : V^n_k \to V^n_0 \) is a 2 to 1 branched cover or a conformal homeomorphism depending on whether \( k = 0 \) or not.

Note that \( g_n \) usually is the result of a different number of iterates of \( f \) when restricted to different \( V^n_k \). However, since we often refer to the map \( g_n \) as acting on individual pieces, it is typographically convenient to introduce the notation

**Definition:** The map \( g_{n|V^n_k} = f^{or_{n,k}} \) will be denoted \( g_{n,k} \).

Thus, \( g_{n,k}(V^n_n) = V^n_0 \) is a 2 to 1 branched cover or a homeomorphism depending on whether \( k = 0 \) or not.

From this moment on, we will assume that the principal nest is infinite, and that \( f \) is non-renormalizable, thus excluding the possibility of an infinite cascade of central returns. In this situation we say that \( f \) is combinatorially recurrent.

### 2.7. Paraneast

The paraneast is well defined around parameters \( c \) outside the main cardioid that are neither immediately renormalizable nor postcritically finite.

**Definition:** If \( c \) is a parameter such that \( f_c \) has a well defined nest up to level \( n \) (for \( n \geq 0 \)), the paraneast piece \( \Delta^n[c] \) is defined by the condition \( \partial \Delta^n[c] = \partial f_c(V^n_0) \); where \( V^n_0 \) is the central piece of level \( n \) in the principal nest of \( f_c \). By the Douady-Hubbard theory, \( \Delta^n[c] \) is a well defined region.

The definition of principal nest, together with Proposition 2.3 imply that when \( c' \in \Delta^n[c] \), the principal nests of \( f_c \) and \( f_{c'} \) are identical until the first return \( g_n(0) \) to \( V^n_0 \) (which creates \( V^n_0 \)). In fact, the relevant pieces move holomorphically as \( c' \) varies and \( \Delta^n[c] \) is the largest parameter region over which the initial set of \( \ell_n \) iterates of \( 0 \) (recall that \( g_n \equiv f^{or_{n}} \)) moves holomorphically without crossing piece boundaries.

Following the presentation of [L3], the family \( \{ g_n[c'] : V^n_0[c'] \to V^n_0[c'] \mid c' \in \Delta^n[c] \} \) is a proper DH quadratic-like family with winding number 1. The last property follows from Proposition 2.3 since \( g_n \) is the first return to a critical piece at this level.

Since the central nest pieces are strictly nested, the above definition implies that the pieces of the paranest are strictly nested as well. It follows that \( (\text{int } \Delta^n) \setminus \Delta^{n-1} \) is a non-degenerate annulus. One of the main concerns is to estimate its modulus or, as it is sometimes called, the paramodulus.

### 3. Frame system

Let \( f_c \) have an infinite principal nest. For real parameters, Lyubich provides in [L1] a complete criterion for compatibility between consecutive nest levels. Since the Julia set is an interval when \( c \in \mathbb{R} \), the compatibility conditions are given in terms of the left/right location of lateral pieces (relative to \( 0 \)) and the orientation of each \( g_{n,k} \) (as an interval map).

In the case of a complex parameter, the nest falls short of being a complete invariant for the dynamics of the critical orbit. The reason is that the nest description does not account for the relative positions between lateral pieces. In contrast to the real case, the Julia set of a complex polynomial displays a complicated structure that varies with the parameter. Lateral pieces may be attached to different branches of the Julia set. For this reason, a record of the relative positions of nest pieces must be preceded by a description of the combinatorial structure around them.

In this Section we enhance the principal nest with the addition of a frame system. This provides the necessary language to locate the lateral nest pieces and describe as a consequence, the behavior
of the critical orbit. The idea is to split the central nest pieces in smaller regions by a procedure that resembles the construction of the puzzle.

For convenience, let us summarize certain aspects of the construction before giving it in detail. Recall that the definition of $V_0^0$ guarantees that $(\text{int} Y_0^{(1)}) \setminus V_0^0$ is a non-degenerate annulus. Because of this initial step, and since our purpose is that frame levels correspond to nest levels, we need to pay individual attention to the construction of the first three levels of the frame. Figure 5 illustrates these initial steps. We will keep in mind our convention of distinguishing between puzzle depths and nest levels. Accordingly, frames will be also stratified in levels since their definition depends on the same pull backs as those used for the nest. To distinguish between nest pieces and frame pieces, the latter will be referred to as cells. As a final note of warning, we will abuse our notation and use $F_n$ to refer to the frame as well as to the system of curves that bound its cells. In particular, we will use $\partial F_n$ to describe the union of curves that form the boundary of the union of all cells in $F_n$. The context will always make clear which meaning is intended.

3.1. Frames. As mentioned above, some attention must be given to the construction of the frames $F_0$, $F_1$ and $F_2$ so that the properties in Proposition 3.3 hold. Figure 5 provides a useful reference. After this, the frames of higher levels are defined inductively.

Consider the puzzle partition at depth 1 and recall that $kq$ denotes the first escape of the critical orbit to $Z_\nu$. The initial frame $F_0$ is the collection of nest pieces $F_0 = \{ Y_0^{(1)} \} \cup \{ \bigcup_{j=1}^q \{ Z_j \} \}$, each of which is called a frame cell. In particular, $\Gamma(F_0)$ is a $q$-gon. The frame $F_1$ is the collection of $f^{\circ kq}$-pull backs of cells in $F_0$ along the orbit of 0.

From the definition, one of the cells of $F_1$ is the central piece $V_0^0$ that maps 2 to 1 onto $Z_\nu \in F_0$. The pull back of any other cell $A \subset F_0$ consists of two symmetrically opposite cells, each mapping univalently onto $A$. We say that $F_1$ is a well defined unimodal pull back of $F_0$.

Lemma 3.1. All the cells of $F_1$ are contained in $Y_0^{(1)}$.

Proof: Since $kq > 1$, $f^{\circ kq}(Y_0^{(1)})$ is an extension of $Y_0^{(0)}$ to a larger equipotential. Thus, $f^{\circ kq}(Y_0^{(1)})$ contains all cells of $F_0$.

Let $\lambda$ be the first return time of 0 to a cell of $F_1$. By Lemma 3.1, the collection $F'_2$ of pull backs of cells in $F_1$ along the $f^{\circ \lambda}$-orbit of 0 is well defined and 2 to 1. Unfortunately, it does not cover every point of $J_f$ inside $V_0^0$. We will give first some results about $F'_2$ and define afterward a complete frame of level 2.

Lemma 3.2. The temporary frame $F'_2$ satisfies:

1. All cells of $F'_2$ are contained in $V_0^0$.
2. $V_0^1$ is contained in the central cell of $F'_2$.

Proof: First note that $\lambda = kq + (q - \nu)$ is the first return of 0 to $Y_0^{(1)}$ after the first escape to $Z_\nu$. We have $kq < \lambda \leq \ell_0$, where the second inequality is true since $V_0^0 \subset F_1$. Then the first return to $F_1$ occurs no later than the first return to $V_0^0$. By definition, $f^{\circ \lambda}(V_0^0)$ is just $Y_0^{(0)}$ extended to a larger equipotential. Since all cells of $F_1$ are inside $Y_0^{(1)} \subset f^{\circ \lambda}(V_0^0)$, the first assertion follows.

Now, $V_0^1$ is central. By the Markov properties of $Y_\nu$, either $V_0^1$ is contained in the central cell $C$ of $F'_2$ or vice versa. However, both $f^{\circ \lambda}(V_0^1)$ and $f^{\circ \lambda}(C)$ belong to $F_1$. Since $\ell_0 \geq \lambda$, the first possibility is the one that holds. This proves property (2).}

Our intention is to extend $F'_2$ to a frame that covers the intersection $J_f \cap V_0^0$. To do this, we just need to add the $f^{\circ \lambda}$-pull backs of the pieces $Z_\nu$. The union of those pull backs with the cells of $F'_2$ is the frame $F_2$.  

11
Figure 5. Both of these parameters belong to the left antenna of $L_{1/3}$; they are centers of components of periods 7 and 4. Above we can see that the structures of the frames of levels 0 and 1 coincide between the two examples. Still, the first return to $F_1$ falls in each case on a different cell, producing dissimilar frames of level 2. The pull back of cells in $F_1$ produces a preliminary frame $F_2'$, shown in heavy line on the second row. The complete frame $F_2$, inside $V_0^n$ has $2(q-1)$ additional cells (here $q = 3$) in order to cover all of $J_f \cap V_0^n$.

After introducing the first frames and relating them to the initial levels of the nest, we can give the complete definition of the frame system. The driving idea of this discussion is that the internal structure of a frame $F_{n+2}$, represented by the graph $\Gamma(F_{n+2})$, provides a decomposition of $J_f \cap V_0^n$ that helps to describe the combinatorial type of the nest at level $n + 1$.

Definition: For $n \geq 0$ consider the first return $g_n(0) \in V_0^n$ and define $F_{n+3}$ as the collection of $g_n$-pull backs of cells in $F_{n+2}$ along the critical orbit. The family $F_c = \{F_0, F_1, \ldots\}$ is called a frame system for the principal nest of $f_c$ and each piece of a frame is called a cell.
The dual graph $\Gamma(F_n)$ (see Subsection 2.3) is called the **frame graph**. As in the case of the puzzle graph, we consider $\Gamma(F_n)$ with its natural embedding in the plane.

Let us mention now some properties of frame systems.

**Proposition 3.3.** The frame system satisfies:

1. Frames exist at all levels.
2. The union of cells $\bigcup_{C_i \in F_n} C_i$ forms a cover of $K_f \cap V_0^{n-2}$.
3. The central cell of $F_n$ contains the nest piece $V_0^{n-1}$.
4. Each $F_n$ has 2-fold central symmetry around 0.
5. Suppose there is a non-central return; then, eventually all nest pieces are compactly contained in cells of the corresponding frame.

The following observation will help clarify the definition of frames (also, refer to Figure 3). As follows from the comment after Lemma 3.1, the union of cells in $F_2$ covers exactly the intersection of $K_f$ with the nest piece $V_0^0$. This is because $V_0^0$ can be described as the pull back of $Y_0^{(0)}$ under the first return map to $F_1$. Then, we can think of this union of cells as a single piece, determined by the same rays as $V_0^0$, but cut off by a lower equipotential.

**Proof of Proposition 3.3.** $F_0$ and $F_1$ are easily seen to exist from their construction. Since $F_1$ covers the central part of $K_f$ between $\alpha$ and $-\alpha$, there will definitely be a return to it, creating $F_2'$.

As we saw already, this frame is contained inside $V_0^0$, so its pull backs are well defined as long as there are new levels of the nest. In particular, this already proves claim 2. Since the principal nest is infinite, the critical point is recurrent or the map is renormalizable. Either case creates critical returns to central nest pieces of arbitrarily high level, so $F_{n+1}$ is defined.

The piece $V_0^0$ is actually the central cell of $F_1$. Now, the first return to $F_1$ cannot occur later than the first return to $V_0^0$, so the central cell $C$ of $F_2$ is of lower depth than $V_0^1$; thus, $V_0^1 \subset C$. Afterwards, the depth from $V_0^{n-1}$ to $V_0^n$ increases by $\ell_{n-1}$, while the depth from $F_n$ to $F_{n+1}$ increases $\ell_{n-2}$. Inductively, since $V_0^{n-1} \subset F_n$ and $\ell_{n-2} \leq \ell_{n-1}$, we obtain $V_0^n \subset F_{n+1}$.

Now, each $F_n$ is a well defined 2 to 1 pull back of $F_{n-1}$; so a cell $C$ belongs to $F_n$ if and only if its symmetric $-C \in F_n$. Finally, Part 5 follows in a similar manner to the analogous property of $V_0^0$ inside $Y_0^{(0)}$.

3.2. **Frame labels.** Our next objective is to introduce a labeling system for pieces of the frame. This will allow us to describe the relative position of pieces of the nest within a central piece of the previous level. Unlike the case of unimodal maps, where nest pieces are always located left or right of the critical point, the possible labels for vertices of $\Gamma(F_n)$ will depend on the combinatorics of the critical orbit. Only after determining the labeling, it becomes possible to describe the location of nest pieces in a systematic manner.

Observe that the structure of $F_{n+1}$ is trivially determined once we know $F_n$ and the location of $g_n(0)$. A graphic way of seeing this is as follows. Say that the first return $g_{n-1}(0)$ to $V_0^{n-2}$ falls in a cell $X \in F_n$. Let $L_n$ and $R_n$ be two copies of $\Gamma(F_n)$ with disjoint embeddings in the plane. Now connect $L_n$ and $R_n$ with a curve $\gamma$ that does not intersect either graph. Suppose that one extreme of $\gamma$ lands at the vertex of $L_n$ that corresponds to $X$ and the other extreme lands at the corresponding vertex of $R_n$ approaching it from the same access.

**Lemma 3.4.** If $\gamma$ is collapsed by a homotopy of the whole ensemble, the resulting graph is isomorphic to $\Gamma(F_{n+1})$.

**Note:** The above construction provides $\Gamma(F_{n+1})$ with a natural plane embedding; see lemma 3.5 below.
A label at level \( n \) will be a chain of \( n + 1 \) symbols taken from the alphabet \( \{0, 1, \ldots, (q-1), l, r, e, b, t\} \). First, put the labels \( \{'0', '1', \ldots, '(q-1)'\} \) on the cells of \( F_0 \), starting at the central piece \( Y_{0}^{(0)} \) and moving counterclockwise.

Let \( \sigma_0 \) be the label of the cell that holds the first return of 0 to \( F_0 \) and, in general, let \( \sigma_n \) denote the label of the cell in \( \Gamma(F_n) \) that holds the first return of 0. In order to label \( \Gamma(F_{n+1}) \), assume that we know the number \( q \) of pieces in \( F_0 \), and the label sequence \( (q; \sigma_0, \ldots, \sigma_{n-1}) \) that identify the location of first returns of 0 to levels 0, \ldots, \( n - 1 \) of the nest. In particular, all frames up to \( \Gamma(F_n) \) have been successfully labeled.

Duplicate in \( L_n \) the labels of \( \Gamma(F_n) \), but concatenate an extra '$l$' at the beginning. Do a similar labeling on \( R_n \) by concatenating an extra '$r$' to the duplicated labels. Note that the labels of the two vertices corresponding to \( X \) are '$l'\sigma_n$ and '$r'\sigma_n$. The labels on \( \Gamma(F_{n+1}) \) will be the same as those in the union of \( L_n \) and \( R_n \) except that we change the label of the identified vertex, to become '$0'\sigma_n$.

Note: The above procedure does not give labels to the additional cells of \( F_2 \) that do not come from a pull back. These are the cells that are not drawn in heavy line in Figure 5. Being cells of level 2, their labels should have 3 symbols for consistency with the rest. The easiest way to do this is simply to impose the labels '$et1$', '$et2$', \ldots, '$et(q-1)$' and '$eb1$', '$eb2$', \ldots, '$eb(q-1)$' in their natural order in the plane ('et' stands for extra piece on top and 'eb' for extra piece on bottom), then extend the labeling to higher levels as described.

Clearly, \( f \) induces a map \( f_* : \Gamma(F_{n+1}) \to \Gamma_n \) for \( n \geq 2 \), that acts by forgetting the leftmost symbol of each label. This is the case also for the induced map on the temporary frame \( F'_2 \).

3.3. Properties of frame labellings. Under certain conditions, label sequences give a complete characterization of the entire combinatorial structure. This is the content of Theorem \footnote{This is a numbered footnote.}. Before stating it, we need to review some properties of the frame and its labels.
Lemma 3.5. The plane embedding of $\Gamma$ does not depend on the homotopy class of the curve $\gamma$ in lemma 3.4.

Proof: Since we regard $\Gamma = \Gamma(F_n)$ as embedded in the sphere, the exterior of $\Gamma$ is simply connected, so there is a natural cyclic order of accesses to vertices (some vertices can be accessed from more than one direction). In this order, all accesses to $L_n$ are grouped together, followed by the accesses to $R_n$. \hfill \square

It is important to mention that the resulting labeling of $\Gamma(F_n)$ does depend on the access to $\xi_n$ approached by $\gamma_j$. However, the final unlabeled graphs are equivalent as embedded in the plane.

As we just mentioned, some vertices are accessible from $\infty$ in two or more directions. These are precisely the vertices whose label contains the symbol '0' (for $n \geq 1$). Since such a vertex represents a frame cell that maps (eventually) to a central frame cell, the tail of a label with '0' at position $j$ must be $\sigma_j$. On the other hand, for every $j$ there must be labels with a '0' in position $j$. It follows that the set of labels of $\Gamma(F_n)$ and the sequence $(q; \sigma_0, \ldots, \sigma_n)$ can be recovered from each other.

3.4. Frames and nest together. The definition of frame system was conceived to satisfy the properties of Proposition 5.3. An extension of the argument used to prove those properties shows that every piece $V_j^n$ of the nest is contained in a frame cell of level $n + 1$. Moreover, we would like to extend the definition of frames so that each $V_j^n$ can be partitioned by a pull back of an adequate central frame. For this, we must recall first that $g_{n,j}(V_j^n) = V_0^{n-1} \supset F_{n+1}$.

Definition: The frame $F_{n,k}$ is the collection of pieces inside $V_k^{n-2}$ obtained by the $g_{n-2,k}^{-1}$ pull back of $F_{n-1}$. Elements of the frame $F_{n,k}$ are called cells and we will write $F_{n,0}$ instead of $F_n$, when there is a need to stress that a property holds in $F_{n,k}$ for every $k$.

If a puzzle piece $A$ is contained in a cell $B \in F_{n,k}$, we denote $B$ by $\Phi_{n,k}(A)$.

We have described already how to label $F_n$. The other frames $F_{n,k}$ ($k \geq 1$), mapping univalently onto $F_{n-1}$, have a natural labeling induced from that of $F_{n-1}$ by the corresponding $g_{n-2,k}$ pull back.

Let us describe now the itinerary of a piece $V_j^n$. Since $V_j^n \subset V_0^{n-1}$, the map $g_{n-1}$ takes $V_j^n$ inside some piece $V_{k_j}^{n-1} \subset V_0^{n-2}$. Then, $g_{n-1,k_j}(j)$ takes $g_{n-1}(V_j^n)$ inside a new piece $V_{k_{j+1}}^{n-1}$ and so on, until the composition of returns of level $n - 1$

$$(g_{n-1,k_r}(j) \circ \ldots \circ g_{n-1,k_1}(j) \circ g_{n-1})|_{V_j^n}$$

does not depend on the homotopy class of the curve $\gamma_j$. Of course, $k_r$ is just 0, and we will write it accordingly.

We have extra information that deems this description more accurate. For the sake of typographical clarity, we will write $k_i$ instead of $k_i(j)$. For $i \leq r$, let $\Phi_{n+1,k_i}$ be the cell in $F_{n+1,k_i} \subset V_{k_i}^{n-1}$ that contains $g_{n-1,k_i} \circ \ldots \circ g_{n-1,k_1}(V_j^n)$ and denote by $\lambda_{n+1,k_i}$ the label of $\Phi_{n+1,k_i}$.

Definition: The itinerary of $V_j^n$ is the list of piece-label pairs:

$$(\lambda(V_j^n) = \left(\left[V_{k_1}^{n-1}; \lambda_{n+1,k_1}\right], \left[V_{k_2}^{n-1}; \lambda_{n+1,k_2}\right], \ldots, \left[V_{k_r}^{n-1}; \lambda_{n+1,k_r-1}\right], \left[V_0^{n-1}; \lambda_{n+1,0}\right]\right)$$

up to the moment when $V_j^n$ maps onto $V_0^{n-1}$.

Note first of all that the last label, $\lambda_{n+1,0}$, will start with '0' due to the fact that $V_0^{n-1}$ is in the central cell of $F_n$. More importantly, the conditions

$$(V_{k_1}^{n-1} \subset g_{n-1}(\Phi_{n+1,0}), V_{k_i}^{n-1} \subset g_{n-1,k_i}(\Phi_{n+1,k_i}) \quad 2 \leq i < r)$$

15
must hold since we know that \( g_{n-1,k_i} \circ \ldots \circ g_{n-1,k_1} \circ g_{n-1}(V^n) \subset \Phi_{n+1,k_i} \) and \( g_{n-1,k_i} \circ \ldots \circ g_{n-1,k_1} \circ g_{n-1}(V^n) \subset V^{n-1}_{k_{i+1}} \).

**Definition:** When we specify the sequence of frame labellings up to a given level \( n \), the locations of the nest pieces and their (admissible) itineraries, we say that we have described the **combinatorial type** of the map at level \( n \). If \( |V^n| < \infty \) we say that the type is **finite**; refer to Lemma 2.6 and Definition 2.6.

Condition 3.2 will be called the **frame admissibility condition**.

### 3.5. Real frames.

Let us digress momentarily in order to compare the above definitions with their counterparts in the real case.

When the parameter \( c \) is real, all the pieces of the nest intersect the real axis. Call \( I^n_j \) the intersection of \( V^n_j \) with \( \mathbb{R} \). The combinatorial type of the nest is determined by how many intervals are there left and right of \( I^n_0 \), the sign (orientation) of each map \( g_{n,j} : I^n_j \rightarrow I^{n-1}_0 \) and the itineraries of all \( I^n_j \) through intervals of the previous level. If we specify an arbitrary type, the **unimodal admissibility conditions** are necessary so that the type can be realized; these conditions require

- Since \( g_{n-1,k} \) is supposed to take \( I^{n-1}_k \) onto \( I^{n-2}_0 \), the order of the intervals inside \( I^{n-1}_k \) is preserved or reversed according to the orientation of \( g_{n-1,k} \).
- Since \( g_{n,j} : I^n_j \rightarrow I^{n-1}_0 \) is supposed to be the composition of all \( g_{n-1,k_i} \) specified by the itinerary of \( I^n_j \), the sign of \( g_{n,j} \) must be the product of signs of the \( g_{n-1,k_i} \) when \( I^n_j \) is right of \( I^n_0 \) and the negative of that sign when \( I^n_j \) is to the left of \( I^n_0 \) (or the other way, if \( g_{n,0} \) reverses orientation).

![Figure 7](image-url)

**Figure 7.** Illustration of the unimodal admissibility conditions. The map \( g_{n-1,0} \) spreads the intervals of level \( n \) inside some intervals of level \( n-1 \). However, the order of the right intervals is respected and that of the left intervals is reversed. Note that the orientation of each left interval is also reversed and that \( I^n_0 \) maps to the leftmost position.

We note first that both conditions emphasize the fact that \( g_{n,0} \) is unimodal. The first map \( g_{n-1,0} \) can mix left intervals with right intervals as in Figure 7 but the order of the right intervals is preserved and the order of the left ones is reversed (or vice-versa). The second condition specifies that the orientation of each \( g_{n,j} \) is the product of the orientations of all intermediate steps **including the fact that** \( g_{n-1,0} \) **has different orientations on each side of 0**. The important observation to make is that the simplicity of the unimodal admissibility conditions is due to the existence of a natural order on \( \mathbb{R} \). In the more general case of complex polynomials, the order of intervals is replaced...
by relative locations of nest pieces within a frame. The requirement that relative orders are preserved is replaced by Conditions 3.2 and the rule of signs is replaced by a compatible choice of labels.

3.6. Combinatorial classification. We are ready to state the main theorem of this Section. In loose language, it states the existence within the quadratic family, of arbitrary admissible finite combinatorial types.

Definition: We will say that two non-renormalizable polynomials are weakly combinatorially equivalent if they have the same combinatorial types at every level, so that they differ only by the orientation of their frames.

Note: The point \( g_n(0) \) is contained in \( V_0^{n-1} \). In particular, it is possible to apply the map \( g_{n-1} \) to it and, in fact, we could keep composing first return maps of lower levels until the first return of the critical orbit to \( V_0^n \). This argument shows that for weak combinatorially equivalent maps, \( g_{n+1} \) is formed by the same composition of previous levels first return maps and consequently, the first returns to corresponding pieces happen at the same times. In the next sections we will make use of this property.

**Theorem 3.6.** Consider a finite combinatorial type of level \( n \), together with a parapiece \( \Delta \) of parameters that satisfy it up to level \( n - 1 \). Let \( \ell \) be the level of the last lateral return prior to level \( n \) and let

\[
    r = \begin{cases} 
    1 & \text{if } g_n \text{ is a central return} \\
    2^{n-\ell} & \text{if } g_n \text{ is lateral.}
    \end{cases}
\]

Then there exist \( r \) parapieces inside \( \Delta \) each consisting of parameters satisfying the same weak combinatorial type to level \( n \).

Moreover, for any such parapiece \( \Delta' \), the first returns \( \{ g_n[c] \mid c \in \Delta' \} \) form a full DH quadratic-like family.

Note: This property of accumulating powers of 2 during central cascades is related to the phenomenon that makes Lyubich’s theorem possible. Namely, the fact that the moduli grow linearly from lateral return to lateral return, even though they decrease by half on each central return.

Proof: We are already acquainted with the central symmetry of frames. It is obvious that the dual graph of a frame can be symmetric only about its critical vertex \( \xi_c \). Because of this, the frame \( F_{\ell+1} \) cannot be symmetric around the lateral cell \( C \) where \( g_{\ell}(0) \in \left(V_0^{\ell-1} \setminus V_0^\ell\right) \) falls, so the pull back \( F_{\ell+2} \) cannot have more than 2-fold symmetry around the origin.

By definition, the (possibly empty) sequence \( \{ g_{\ell+1}, \ldots, g_{n-1} \} \) is the beginning of a cascade of central returns of length \( n - \ell \). Therefore, the frame graph \( \Gamma(F_{n+2}) \) has exactly \( (2^n-\ell) \)-fold symmetry around \( \xi_c \).

Let \( c \in \Delta \). Every map \( g_{n-1,k} \) takes its corresponding piece \( V_k^{n-1} \) onto \( V_0^{n-2} \). Then the pull back by \( g_{n-1,k} \) of any region inside \( V_0^{n-2} \) is well defined and located inside \( V_k^{n-1} \). In particular, for every piece \( V_j^\ell \) listed in the type of level \( n \), the itinerary prescribes the sequence of returns \( g_{n-1,0}, g_{n-1,k_1}, \ldots, g_{n-1,k_j} \), so the univalent pull back of \( V_0^{n-1} \) under the composition \( (g_{n-1,k_1} \circ \ldots \circ g_{n-1,k_j}) \) is a well defined piece inside \( V_k^{n-1} \). Let us name this piece \( U'_j \).

Clearly \( U'_0 \subseteq V_1^{n-1} \) because the itinerary of the critical piece \( V_0^n \) begins with the first return of 0 to level \( n - 1 \). As \( c \) moves within \( \Delta \), this return can be made to fall in \( U'_0 \). All \( c \) with this property form a parapiece \( \Delta^* \subseteq \Delta \) that can be described as the set of parameters for which the itinerary of \( U_0 \) is as originally prescribed; i.e. \( U_0 = V_0^n \). For the rest of the argument we will restrict \( c \) to \( \Delta^* \).

For \( j \geq 1 \), the \( g_{n-1,0} \)-pull back of \( U'_j \) will be called \( U_j \); however, \( g_{n-1,0} \) is 2 to 1, so we have to decide on a frame orientation before locating these pieces inside \( F_{n+2} \).
The combinatorial type of level \( n \) involves the label \( \sigma_{n+2} \) that specifies the cell in \( F_{n+2} \) containing the first return \( g_0(0) \). If this return is central there is no choice: The return falls on the piece \( V_{0}^{n+1} \) inside the central cell. Otherwise, we need to recall the discussion above. After a (possibly vacuous) cascade of central returns, there are \( \frac{1}{2} = 2^{n-\ell-1} \) cells of \( F_{n+1,k_1} \) that can be labeled with \( \sigma_{n+2} \) and contain \( U' \). This comes from the \( n - \ell - 1 \) choices of orientation taken from level \( \ell + 1 \) to \( n - 1 \). Assuming that the return \( g_0(0) \) is lateral, there is one more choice of orientation to make, so \( F_{n+2} \) has \( (2^{n-\ell}) \) cells that can host \( U_j \). Once this decision is made, the label orientation is determined and the rest of the pieces \( U_j \) are forcibly placed around the frame \( F_{n+2} \).

We have constructed pieces \( U_j \subset V_{0}^{n-1} \) that follow the given itineraries. It rests now to show that for some parameters \( c \in \Delta^* \), the \( U_j \) can be made to coincide with the respective \( V_j^n \). This can be shown as follows. The itinerary of \( V_0^n \) (and of 0) ends with the first return \( g_0 \) of 0 to \( V_{0}^{n-1} \). This return generates a full family for \( c \in \Delta^* \), so we can choose a parapiece \( \Delta^{**} \) of \( c \) such that \( g_0(0) \in U_1 \).

The second return to \( V_{0}^{n-1} \) is specified by the itinerary of \( U_1 \). From this observation we conclude that \( U_1 = V_1^n \) from the definition of nest. Also, this second return generates a full family for \( c \in \Delta^{**} \), so we can choose an even smaller parapiece \( \Delta^{***} \) of parameters \( c \) such that \( g_0(1) \in U_2 \). This argument can be pursued till the end to obtain the parapiece \( \Delta' \) of values \( c \) for which every \( U_j = V_j^n \). \( \square \)

Repeated application of Theorem 3.6 yields the following.

**Corollary 3.7.** Arbitrary infinite sequences of finite, weak combinatorial types can be realized in the quadratic family, as long as they satisfy the admissibility condition at every level. The set of parameters satisfying the complete type is the intersection of a family of nested sequences of parapieces, with \( 2^n \) of them at every non-central level \( n \).

**Proof:** This is clear, since each \( \Delta \) contains at least one parapiece \( \Delta' \) that satisfies the combinatorial type at level \( n \). The collection of first return maps of level \( n \) for parameters in \( \Delta' \) forms a full family, so we can apply Theorem 3.6 again. An arbitrary choice of orientation at every level gives an infinite nested sequence of parapieces. Evidently, a parameter in the intersection satisfies the prescribed combinatorics at every level.

Every level accounts for one dyadic choice of orientation. Although they are not apparent during central cascades, the previous proof shows that they accumulate to display \( 2^{n-\ell} \) pieces of level \( n \) inside each of the \( 2^\ell \) pieces of (lateral) level \( \ell \). \( \square \)

The set of parameters that are combinatorially equivalent to a given one cannot be completely characterized without some amount of analytical information. Corollary 3.7 describes such set as a collection of nested sequences of parametric pieces, but it does not say whether they intersect in single points or in more complicated regions. The fact that the parapieces shrink to a unique parameter amounts to combinatorial rigidity; this was the strategy of Yoccoz to establish local connectivity in the case of non-renormalizable polynomials. For such parameters, he showed that the sum of paramoduli is infinite, so the set of parameters in the nested intersections of parapieces becomes a Cantor set. In particular, if the type includes no central returns, every parapiece contains exactly two pieces of the next level and the Cantor set has a natural dyadic structure. Thus, for some precise sequences of combinatorial types, the choice of frame orientations at every level may single out a unique parameter.

**Note:** It should be remarked that alternative classifications of combinatorial properties are possible and indeed quite useful. Of particular notice is D. Schleicher’s concept of internal addresses (see [LS]), describing a combinatorial type in terms of an irreducible sequence of hyperbolic components that encodes the critical orbit information with increasing precision.
4. Examples

We present here two instances of the use of our combinatorial model. Every first renormalization type corresponds to a maximal hyperbolic component of the Mandelbrot set; these are classified in \(4.1\). A rotation-like map is an unimodal map whose postcritical set is semi-conjugate to a circle rotation; the Fibonacci map being an instance. In \(4.2\) we find complex quadratic maps with the same property. Other applications, including a classification of complex quadratic Fibonacci polynomials, can be found in [P].

4.1. Maximal hyperbolic components. Consider an arbitrary combinatorial type up to some level \(n\), with the property that the last return is not central. Upon specifying a frame orientation, there is a unique parapiece \(\Delta\) consisting of parameters that satisfy the given combinatorics. Clearly, parapieces corresponding to different types must be disjoint.

When the return to level \(n+1\) is central, there is no need to orient the frame; that is, there is a unique piece \(\Delta' \subset \Delta\) of parameters featuring this central return. Then, if a parameter in \(\Delta\) has an infinite cascade of central returns starting at level \(n+1\), its combinatorial type will be completely determined by the initial \(n\) levels. The unique sequence of nested parapieces \(\Delta \supset \Delta' \supset \ldots\) intersects in the set \(M'\) of renormalizable parameters whose first \(n\) nest levels are as prescribed. It is known that \(M'\) is quasi-conformally homeomorphic to \(M\) (see [DH1] and [L3]). In fact, this homeomorphism is given by straightening: For every \(c \in M'\) there is a quasi-conformal map \(h\) that realizes the conjugation \(h \circ g_n = f \circ h\) between \(g_n[c]\) and some quadratic polynomial \(f\); moreover, \(h\) satisfies \(\partial h = 0\) on the small filled Julia set of \(g_n[c]\).

Since the parameters in \(M'\) have a well defined nest, the renormalization is not of immediate type. The base of such “small copy” of \(M\) is a primitive hyperbolic component \(H\). Since \(H\) is a quasi-conformal deformation of \(♥\), its boundary has a cusp point. Also, the parameters in \(H\) are exactly once renormalizable, so \(H\) is maximal (see definitions at the beginning of Section 2).

The above discussion shows that any finite frame type is associated to a maximal hyperbolic component of \(M\). Conversely, each maximal copy of \(M\) is encoded by the type of its frame, that is, by the associated graph \(\Gamma(F_{n+1})\) or its label sequence. Note that the frame graph of level \(n' > n\) consists of a bouquet of \(2^{n'-n}\) copies of \(\Gamma(F_{n+1})\) with their central vertices identified. This is illustrated in the right hand example in Figure 5. The beautiful pictures of small Mandelbrot copies with hundreds of mini-copies spiraling in all directions belong naturally to the class of finite nest types that conclude with a long central cascade.

4.2. Rotation-like maps. Let \(c_{\text{fib}} = -1.8705286321\ldots\) parametrize the Fibonacci map \(z \mapsto z^2 + c_{\text{fib}}\). This is the unique real quadratic polynomial with the property that the critical orbit has closest returns to 0 exactly when the iterates are the Fibonacci numbers; see [LM]. In terms of the principal nest, \(f_{c_{\text{fib}}}\) satisfies the equivalent condition:

For \(n \geq 2\), each level of the principal nest consists of the central piece \(V_0^n\) and a unique lateral piece \(V_1^n\). The first return map of previous level \(g_{n-1}: V_0^{n-1} \to V_0^{n-2}\) interchanges the central and lateral roles:

\[
g_{n-1}(V_0^n) \subseteq V_1^{n-1}, g_{n-1}(V_1^n) = V_0^{n-1}.
\]

Additionally, the first returns to \(Y_0^{(1)}\) and \(V_0^0\) happen on the third and fifth iterates respectively.

To discern the critical orbit behavior of \(f_{c_{\text{fib}}}\), note that every level of the nest has a unique lateral piece and so, in a sense, every first return comes as close as possible to being central without actually being so. This means that the map \(f_{c_{\text{fib}}}\) is not renormalizable in the classical sense, although its
combinatorics can be described as an infinite cascade of *Fibonacci renormalizations* in the space of \textsf{gql} maps with one lateral piece.

The Fibonacci map features as a decisive case in the proof of Lyubich’s theorem; see [L2]. Here we will describe a family of unimodal maps with similar behavior and extend it to a family of complex quadratic maps.

Let \( S = (S_0, S_1, \ldots) \) be a strictly increasing sequence of numbers such that \( \frac{S_{k+1}}{S_k} \leq 2 \). The *S-odometer* is a symbolic dynamical system \((\Omega, T)\) defined as follows. For any nonnegative \( n \) there is a \( k \) such that \( S_k \leq n < S_{k+1} \). Then \( n = S_k + n_1 \) with \( n_1 < S_k \). By splitting further \( n_1 = S_{k'} + n_2 \) (with \( k' < k \) and \( n_2 < S_{k'} \)) and so on, we obtain the decomposition

\[
  n = d_k \cdot S_k + \ldots + d_0 \cdot S_0
\]

where each \( d_j \) is either 0 or 1. Letting \( d_j = 0 \) for \( j > k \), we get the sequence

\[
  \langle n \rangle = (d_0, d_1, \ldots) \in \{0, 1\}^\mathbb{N}.
\]

We use \( \langle \mathbb{N} \rangle \) to denote \( \{\langle n \rangle | n \in \mathbb{N}\} \) and let \( \Omega \) be the closure

\[
  \Omega = \overline{\langle \mathbb{N} \rangle} = \{\omega \in \{0, 1\}^\mathbb{N} | \sum_{i=0}^{j} \omega_i S_i < S_{j+1} \text{ for all } j \geq 0\}.
\]

The map \( T : \langle \mathbb{N} \rangle \to \langle \mathbb{N} \rangle \) is given by \( T(\langle n \rangle) = \langle n + 1 \rangle \). This map does not always extend uniquely to \( \Omega \). When there is an extension, the dynamical system \((\Omega, T)\) obtained from the sequence \( S \) is called a *S-odometer*. It can be described as an adding machine with variable stepsize.

Let us relate the above concept to interval dynamics. First, some definitions.

Consider a unimodal map \( f : I \to I \) where \( I = [c_1, c_2] \) and \( \{0, c_1, c_2, \ldots\} \) is the critical orbit. Let \( D_1 = [c_1, 0] \) and, for \( n \geq 2 \), define

\[
  D_{n+1} = \begin{cases}
    [c_{n+1}, c_1] & 0 \in D_n \\
    f(D_n) & 0 \notin D_n
  \end{cases}
\]

The sequence \( S = (S_0, S_1, \ldots) \) of *cutting times* consists of those \( n \) such that \( 0 \in D_n \). Note that \( S_0 = 1 \). It is easy to show that \( S_{k+1} - S_k \) is also a cutting time so we can define the *kneading map* \( Q : \mathbb{N} \to \mathbb{N} \) by the relation

\[
  S_{Q(k)} = S_{k+1} - S_k.
\]

**Lemma 4.1.** If \( S \) is the sequence of cutting times of a unimodal map \( f \), the following characterization of \( \Omega \) holds:

\[
  \Omega = \{\omega \in \{0, 1\}^\mathbb{N} | \omega_j = 1 \Rightarrow \omega_i = 0 \text{ for } Q(j + 1) \leq i \leq j - 1\}.
\]

Also, if \( Q(k) \to \infty \), then \( T \) extends uniquely to \( \Omega \) and is conjugate to the action of \( f \) on its postcritical set.

See [BKP] for proofs.

In the case of the Fibonacci polynomial, the above definitions correspond to the description of the critical orbit in Subsection 3 of [LM]. There it is shown that \((\Omega, T)_{\text{fib}}\) is semiconjugate to the circle rotation by \( \rho = \sqrt{5} - 1 \). Real *rotation-like maps*, as defined in [BKP], are unimodal maps that generalize this behavior.

Let \( \rho \in [0, 1) \setminus \mathbb{Q} \) with continued fraction expansion \( \rho = [a_1, a_2, \ldots] \) and denote its convergents with \( p_i/q_i \) so that \( p_0/q_0 = 0 \) and \( p_1/q_1 = 1/a_1 \).
Theorem 4.2. [BKP] Consider the sequence \( r_k \) starting with \( r_1 = q_1 - 1 \) and whose \((k+1)\)th element is given recursively by \( r_{k+1} = r_k + a_{k+1} \). Then the \( S \)-sequence given by

\[
S_{r_k} = q_k \\
S_{r_{k+j}} = (j+1)q_k \quad \text{for} \quad 1 \leq j < a_{k+1}
\]

is realized as the sequence of cutting times of some quadratic polynomial. Moreover, the application

\[
\Pi_\rho(\omega) = \sum \omega_j S_j \rho \pmod{1}
\]

from \( \Omega \) to the unit circle is well defined and continuous. This map satisfies \( \Pi_\rho \circ T = R_\rho \circ \Pi_\rho \), where \( R_\rho \) is the rotation by angle \( \rho \), and is 1 to 1 everywhere except at the preimages of 0.

In terms of the principal nest, the behavior that characterizes rotation-like maps is a succession of central cascades followed by one lateral escape. That is, the critical orbit falls in \( V_0^{S_k-1} \) starting a central cascade. After iterating the first return map \( g_k \) for \( a_k - 1 \) turns, we get a lateral return on \( V_1^{S_k} \). Next, \( g_{S_k,1} \) creates a new cascade and so on. In particular, the Fibonacci map is the special case of a rotation-like map where every central cascade has length 0.

Consider an arbitrary sequence \( a_1, a_2, \ldots \) of positive integers. We will construct now a Cantor set of complex rotation-like parameters with central cascades of length \( a_i - 1 \). By theorem 3.6, it is only necessary to give an admissible description of labeling sequences and to show that it models the combinatorics mentioned above.

The initial labeling data for our map is \( q = 2 \) and \( \sigma_0 = '1' \), so rotation-like maps will all be located in the 1/2-limb. Note also that on central return levels, \( \sigma_{k+1} = '0' \sigma_k \). Therefore, we only need to specify the labels \( \sigma_{r_k} \) for \( r_k = \sum a_j \).

Let \((\tau_1, \tau_2, \ldots)\) be a sequence of random chains of \('1'\)’s and \('r'\)’s so that \( \tau_1 \) has length \( a_1 + 1 \). Set \( \sigma_{r_1} = \tau_1'0' \) and \( \sigma_{r_2} = \tau_2 \sigma_{r_1-1} = \tau_2'00 \ldots 01' \). Now we can define inductively \( \sigma_{r_j} = \tau_j'0' \sigma_{r_{j-1}-1} \).

Proposition 4.3. The label sequence \((q; \sigma_0, \sigma_1, \ldots)\) defined above is admissible, it completely describes a combinatorial type and the corresponding map is rotation-like.

Proof: The fact that the sequence of labels determines the type can be seen to be true since there are no consecutive lateral returns. This implies that the nest has exactly one lateral piece at those levels (and none elsewhere) so its position within the frame is completely determined by \( \sigma_{r_j} \).

As mentioned above, \( '0' \sigma_k \) (when \( k \neq r_j \)) is an admissible label since it corresponds to the central cell of \( F_{k+1} \). Now consider what happens to the central cell labeled \( '0' \sigma_{r_{j-1}-1} \). Since level \( r_{j-1} \) corresponds to a non-central return, \( F_{r_{j-1}+1} \) has two preimages of that cell, labeled \( '00' \sigma_{r_{j-1}-1} \) and \( 'r0' \sigma_{r_{j-1}-1} \) respectively. On consecutive central returns, we double the number of pull-backs of such cells and thus, use all possible combinations of \('l'\) and \('r'\) to label them. A glance to the frame graph shows that these are the cells neighboring the central one (see [Sm]). An eventual lateral return must fall precisely in one of these cells, and this is what happens when \( \sigma_{r_j} = \tau_j'0' \sigma_{r_{j-1}-1} \).

The real rotation-like maps studied in [BKP] correspond to a careful choice of the \( \tau_j \). In fact, it is possible to extract a kneading sequence from the rotation number data. Then, a result of Yoccoz guarantees that there is a unique real polynomial in that combinatorial class.

The complex maps corresponding to other choices of \( \tau_j \)’s have the same weak combinatorial behavior, so the critical orbits of two maps with the same sequence \( a_1, a_2, \ldots \) are conjugate. In particular we obtain the following result.

Corollary 4.4. Given the sequence \( a_1, a_2, \ldots \) there exists an infinite family of complex quadratic polynomials for which the postcritical set is conjugate to an \( S \)-odometer and semi-conjugate to the circle rotation of angle \( \rho = [a_1, a_2, \ldots] \).
A. Holomorphic motions of puzzle pieces and winding number. Consider the following

Definition: Let $X_s \subset \mathbb{C}$ be an arbitrary set and $\Delta \subset \mathbb{C}$ a simply connected domain with $*$ as a base point. A holomorphic motion of $X_s$ over $\Delta$ is a family of injections $h_\lambda : X_s \rightarrow \mathbb{C}$ ($\lambda \in \Delta$) such that for each fixed $x \in X_s$, $h_\lambda(x)$ is a holomorphic function of $\lambda$ and $h_* = id$. For every $\lambda \in \Delta$ we write $X_\lambda$ to denote the set $h_\lambda(X_s)$.

Holomorphic motions are extremely versatile owing to their regularity properties. The motion can always be extended beyond $X_s$ and is transversally quasi-conformal. This is the content of the $\lambda$-lemma.

Theorem A.1. [Sl], [MSS] (the $\lambda$-lemma) For every holomorphic motion $h_\lambda : X_s \rightarrow \mathbb{C}$, there is an extension to a holomorphic motion $H_\lambda : \mathbb{C} \rightarrow \mathbb{C}$. The extension to the closure $\overline{h_\lambda} : \overline{X}_s \rightarrow \mathbb{C}$ is unique. Moreover, there is a function $K(\lambda)$ such that for each fixed $x \in X_s$, $h_\lambda(x)$ is the hyperbolic distance between $*$ and $\lambda$ in $\Delta$.

We are interested in the case when the holomorphic motion is defined over a parapiece $\Delta$ of $M$. In agreement with the notation used in the main body of this work, we use $c$ instead of the classical $\lambda$ to denote parameters in $\Delta$. When an object is defined for any $c \in \Delta$, we express its dependence on the parameter by writing OBJ[$c$].

As mentioned in Section 2, $\Delta$ can be interpreted as the set of parameters for which a given combinatorial behavior holds, up to a return $g(0)$ of the critical orbit to some central piece $V$. In particular, this description provides a natural base point for $\Delta$. Namely, the superattracting parameter $c_0$ for which $g_{c_0}(0) = 0$. The little $M$-copy associated to $\Delta$ can be defined as the set of parameters for which the iterates $\{g_c(0), g_c^2(0), \ldots\}$ remain in $V[c]$ (refer to Subsection 4.1).

The dynamics in the region $N_c$ (defined at the beginning of Subsection 2.1) is always conjugate to $z \mapsto z^2$, so varying the parameter $c \in \mathbb{C}$ provides a holomorphic motion of any specified (open) ray or equipotential. When $c$ is restricted to $\Delta$, the combinatorics require that some rays land together, enclosing the boundary of $V[c]$. Since the intersection $\partial V \cap K$ is a collection of preimages of the fixed point $\alpha$ and these vary holomorphically with $c$, there is a natural holomorphic motion of $\partial V[c_0]$ over $\Delta$. This can be extended to a holomorphic motion $h_c : V[c_0] \rightarrow V[c]$.

The holomorphic motion of a puzzle piece can be viewed as a complex 1-dimensional foliation of the bi-disk

$$\mathbb{V} = \bigcup_{c \in \Delta} V[c] \subset \mathbb{C}^2$$

whose leaves are the graphs of the functions $c \mapsto h_c(p)$ for every $p \in V[c_0]$. Under this interpretation we will write $\{c \mapsto V[c] \mid c \in \Delta\}$ to refer to the motion.

Definition: A correspondence $c \mapsto \phi(c)$ such that $\phi(c) \in V[c]$ determines a section $\phi : \Delta \rightarrow \mathbb{V}$ of the holomorphic motion $h$. It is said to be a proper holomorphic section if it maps $\partial \Delta$ into the torus $\delta \mathbb{V} = \bigcup_{c \in \partial \Delta} \partial V[c]$.

We say that a proper section $\{c \mapsto \phi(c)\}$ has winding number $n$ if the curve $\phi(\partial \Delta)$ has winding number $n$ with respect to the vertical generator of the 1-dimensional homology of $\delta \mathbb{V}$.

In the case $\phi(c) = g_c(0)$, this return map determines a proper section since $g_c(0) \in V[c]$ for all $c$ and $c \in \partial \Delta \Rightarrow g_c(0) \in \partial V[c]$. Each return map $g_c : g_c^{-1}(V) \rightarrow V$ is a quadratic-like map and the associated map

$$g_c : U \rightarrow \mathbb{V},$$

where $U = \bigcup g_c^{-1}(V[c])$, is called a DH quadratic-like family. We can interpret intuitively the fact that a family has winding number $n$ as saying that, as $c$ goes once along $\partial \Delta$, the point $g_c(0)$ goes $n$ times around the (moving) boundary of the piece $V[c]$. 

Appendix
An immediate consequence of extending the holomorphic motion of \( \partial V[c_0] \), is the fact that \( \{g_c \mid c \in \Delta\} \) is a full family; that is, there is a homeomorphism \( \text{Hyb} : \tilde{M} \to \Delta \) from a neighborhood \( \tilde{M} \) of \( M \) to \( \Delta \) with the following property: For every parameter \( c' \in \tilde{M} \), \( g_{\text{Hyb}(c')} \) is hybrid equivalent\(^2\) to \( z \mapsto z^2 + c' \). This of course, justifies the existence of the small \( M \)-copy associated to \( \Delta \).
