(Dated: April 2, 2009)

Refined astrometry measurements allow us to detect large-scale deviations from isotropy through real-time observations of changes in the angular separation between sources at cosmic distances. This “cosmic parallax” effect is a powerful consistency test of FRW metric and may set independent constraints on cosmic anisotropy. We apply this novel general test to LTB cosmologies with off-center observers and show that future satellite missions such as Gaia might achieve accuracies that would put limits on the off-center distance which are competitive with CMB dipole constraints.

Introduction. The standard model of cosmology rests on two main assumptions: general relativity and a homogeneous and isotropic metric, the Friedmann-Robertson-Walker metric (henceforth FRW). While general relativity has been tested with great precision at least in laboratory and in the solar system, the issue of large-scale deviations from homogeneity and isotropy is much less settled. There is by now an abundant literature on tests of the FRW metric, and on alternative models invoked to explain the accelerated expansion by the effect of strong, large-scale deviations from homogeneity (see [1] for a review). Several such models adopt as an alternative the Lemaître-Tolman-Bondi metric (henceforth LTB), that is a model with a spherically symmetric distribution of matter (see for instance [2,3,4,5,6,7,8]). The main motivation for this is the fact that the distance-dependent expansion rate can explain the supernovae Ia excess dimming without a dark energy field.

LTB universes appear anisotropic to any observer except the central one. In every anisotropic expansion the angular separation between any two sources varies in time, thereby inducing a cosmic parallax (CP) effect. This is totally analogous to the classical stellar parallax, except here the parallax is induced by a differential cosmic expansion rather than by the observer’s own movement. Together with the Sandage effect of velocity shift [9][10], CP belongs to the new realm of real-time cosmology, a direct way of testing our universe based on cosmological observations spaced by several years [11][12][13][14][15].

One can expect on dimensional grounds that this differential cosmic expansion generates after an observation time lag of $\Delta t = 10$ years an effect of order $H_0\Delta t = 10^{-9}h$; therefore two sources separated by 1 rad today will show a parallax of $10^{-9}h$ rad $\approx 200h$ $\mu$as in ten years, which is well above the accuracy goal of $10$ $\mu$as set by Gaia (for $V \leq 15$) [16] and other planned missions like SIM [17], JASMINE [18] and VSOP-2 [19]. Adopting Gaia specifications, we show that 106 quasars might be enough to constrain the off-center distance $r_0$ to the 10 Megaparsec scale, similar to or better than any other proposed test of the Copernican principle but without the degeneracy with our peculiar velocity that afflicts the constraints from the cosmic microwave background [3,8]. In this paper we first derive an estimate of CP by intuitive arguments based on a FRW description and then test it with a full numerical integration of light-ray geodesics in LTB models.

Estimating the cosmic parallax. Figure 1 depicts the overall scheme describing a possible time-variation of the angular position of a pair of sources that expand anisotropically with respect to the observer. We label the two sources $a$ and $b$, and the two observation times 1 and 2. In what follows, we will refer to $(t, r, \theta, \phi)$ as the comoving coordinates with origin on the center of a spherically symmetric model. Peculiar velocities apart, the symmetry of such a model forces objects to expand radially outwards, keeping $r$, $\theta$ and $\phi$ constant.

Let us assume now an expansion in a flat FRW space from a “center” $C$ observed by an off-center observer $O$ at a distance $X_0$ from $C$. Since we are assuming FRW it is clear that any point in space could be considered a “center” of expansion: it is only when we will consider a LTB universe that the center acquires an absolute meaning. The relation between the observer line-of-sight angle $\xi$ and the coordinates of a source located at a radial dis-

Figure 1: Overview, notation and conventions. For clarity purposes we assumed here that the points $C, O, a_1, a_2, b_1, b_2$ all lie on the same plane. Comoving coordinates $r$ and $r_0$ correspond to physical coordinates $X$ and $X_0$. 
distance \( X \) and angle \( \theta \) in the \( C \)-frame is
\[
\cos \xi = \frac{X \cos \theta - X_0}{(X^2 + X_0^2 - 2X_0X \cos \theta)^{1/2}},
\]
where all angles are measured with respect to the \( CO \) axis and all distances in this section are to be understood as physical distances.

We consider first two sources at location \( a_1, b_1 \) on the same plane that includes the \( CO \) axis with an angular separation \( \gamma_1 \) as seen from \( O \), both at distance \( X \) from \( C \) (throughout this letter we shall always assume for simplicity that both sources share the same \( \phi \) coordinate). After some time \( \Delta t \), the sources move to positions \( a_2, b_2 \) and the distances \( X \) and \( X_0 \) will have increased by \( \Delta X \) and \( \Delta X_0 \) respectively. If for a moment we allow ourselves the liberty of assigning to the scale factor \( a(t) \) and the \( H \) function a spatial dependence, a time-variation of \( \gamma \) is induced. The variation \( \Delta \gamma \) is the anticipated cosmic parallax effect and can be easily estimated if we suppose that the Hubble law is just generalized to \( \Delta H = XH(t, X) \Delta t \equiv XH X \Delta t \). Generalizing to sources on different shells separated by a small \( \Delta X \equiv X_2 - X_0 \) (not to be mistaken with the time interval \( \Delta X \)) and \( \Delta \theta \equiv \theta_{b1} - \theta_{a1} \), after straightforward geometry we arrive at
\[
\Delta t \gamma = s \Delta t (H_{\text{obs}} - H_X) (\cos \theta \Delta \theta + \sin \theta \Delta X/X)
+ H_X dH_X/dX \sin \theta \Delta O + (s^2).
\]
where \( H_{\text{obs}} \equiv H(t_0, r_0) \), \( s \equiv X_0/X \ll 1 \) (at this order we can neglect the difference between the observed angle \( \xi \) and \( \theta \)). We can also convert the above intervals \( \Delta X \) into the redshift interval \( \Delta z \) by using the relations \( r = \int dz/H(z) \) and \( X = \int a(t, r)dr \), which combine to \( \Delta X = a(t_0, X) \Delta z/H(z) \sim \Delta z/H(z) \) (we impose \( a(t_0, X_0) = 1 \), where \( H(z) = H(t, t(z), X) \).

In a FRW metric, \( H \) does not depend on \( r \) and the parallax vanishes. On the other hand, any deviation from FRW entails such spatial dependence and the emergence of cosmic parallax, except possibly for special observers (such as the center of LTB). A constraint on \( \Delta t \gamma \) is therefore a constraint on cosmic anisotropy.

Rigorously, one actually needs to perform a full integration of light-ray geodesics in the new metric. Nevertheless, we shall assume for a moment that for an order of magnitude estimate we can simply replace \( H \) with its space-dependent counterpart given by LTB models. In order for a LTB cosmology to have any substantial effect (e.g., explaining the SNIa Hubble diagram) it is reasonable to assume a difference between the local \( H_{\text{obs}} \) and the distant \( H_X \) of order \( H_{\text{obs}} \). More precisely, putting \( H_{\text{obs}} - H_X = H_{\text{obs}} \Delta h \) then one has that the overall effect \( \Delta t \gamma \) for on-shell sources is of order \( s \cos \theta H_{\text{obs}} \Delta h \Delta t \Delta \theta \). That is, as anticipated, for \( \Delta t = 10 \) years we expect a parallax of \( 200 s \cos \theta \Delta h \Delta t \Delta \theta \) mas for sources separated by \( \Delta \theta \). Similarly, for radial source pairs, neglecting the \( dH_X/dX \) term (which is valid except close to the edge of the LTB void), one has \( s \sin \theta H_{\text{obs}} \Delta h \Delta t \Delta z/z \approx 200 s \sin \theta \Delta h \Delta z/z \) mas (assuming \( X \approx zH(z) \)).

Let us finally consider the main expected source of noise, the intrinsic peculiar velocities of the sources. The variation in angular separation for sources at angular diameter distance \( D_A \) (measured by the observer) and peculiar velocity \( \upsilon_{\text{pec}} \) can be estimated as
\[
\Delta t \gamma_{\text{pec}} = \left( \frac{\upsilon_{\text{pec}}}{500 \text{ km/s}} \right) \left( \frac{D_A}{1 \text{ Gpc}} \right)^{-1} \left( \frac{\Delta t}{10 \text{ years}} \right) \text{mas}.
\]
This velocity field noise is therefore typically smaller than the experimental uncertainty (especially for large distances) and again will be averaged out for many sources. Notice that the observer’s own peculiar velocity produces a systematic offset sinusoidal signal \( \Delta t \gamma_{\text{pec},O} \) of the same amplitude as \( \Delta t \gamma_{\text{pec}} \) that has to be subtracted from the observations: we discuss this further below.

**Geodesic Equations.** These very suggestive but simplistic calculations need confirmation from an exact treatment where the full relativistic propagation of light rays is taken into account. We will thus consider in what follows two particular LTB models capable of fitting the observed SNIa Hubble diagram and the CMB first peak position and compatible with the COBE results of the CMB dipole anisotropy, as long as the observer is within around 15 Mpc from the center [5]. Moreover, both models have void sizes which are small enough (\( z \sim 0.3 \)) not to be ruled out due to distortions of the CMB blackbody radiation spectrum [20].

The LTB metric can be written as (with primes and dots refer to partial space and time derivatives, respectively):
\[
d s^2 = -d t^2 + \left( \frac{R'(t, r)^2}{1 + \beta(r)} \right) d r^2 + R^2(t, r) d \Omega^2,
\]
where \( \beta(r) \) can be loosely thought as position dependent spatial curvature term. Two distinct Hubble parameters corresponding to the radial and perpendicular directions of expansion are defined as \( H_t = R'/R \) and \( H_r = R/R \) (in a FRW metric \( R = r a(t) \) and \( H_t = H_\perp \)). This class of models exhibits implicit analytic solutions of the Einstein equations in the case of a matter-dominated universe, to wit (in terms of a parameter \( \eta \))
\[
R = (\cosh \eta - 1) \frac{\alpha}{2 \beta} + R_{\text{las}} \left( \cosh \eta + \sqrt{D} \sinh \eta \right),
\]
\[
\sqrt{\beta t} = (\sinh \eta - \eta) \frac{\alpha}{2 \beta} + R_{\text{las}} \left[ \sinh \eta + \sqrt{D} \sinh (\eta - 1) \right],
\]
where \( D = (\alpha + \beta R_{\text{las}})/\beta R_{\text{las}} \), and \( \alpha, \beta \) and \( R_{\text{las}} \) are all functions of \( r \). In fact, \( R_{\text{las}}(r) \) stands for \( R(0, r) \) and we will choose \( t = 0 \) to correspond to the time of last scattering, while \( \alpha(r) \) is an arbitrary function and \( \beta(r) \) is assumed to be positive. Due to the axial symmetry and the fact that photons follow a path which preserves the 4-velocity identity \( u^a u_a = 0 \), the four second-order geodesic equations for \((t, r, \theta, \phi)\) can be written as
five first-order ones. We will choose as variables the center-based coordinates \( t, r, \theta, p = dr/d\lambda \) and the redshift \( z \), where \( \lambda \) is the affine parameter of the geodesics. We shall refer also to the conserved angular momentum \( J \equiv R^2 d\theta/d\lambda = \text{const} = J_0 \). For a particular source, the angle \( \xi \) is the coordinate equivalent to \( \theta \) for the observer, and in particular \( \xi_0 \) is the coordinate \( \xi \) of a photon that arrives at the observer at the time of observation \( t_0 \). Obviously this coincides with the measured position in the sky of such a source at \( t_0 \). In terms of these variables, and defining \( \lambda \) such that \( u(\lambda) < 0 \), the autonomous system governing the geodesics is written as

\[
\frac{dt}{d\lambda} = -\sqrt{\frac{(R')^2}{1+\beta} p^2 + \frac{J^2}{R^2}}, \quad \frac{dr}{d\lambda} = p, \quad \frac{d\theta}{d\lambda} = \frac{J}{R^2}, \quad \frac{dz}{d\lambda} = \sqrt{\frac{(R')^2}{1+\beta} p^2 + \frac{J^2}{R^2}} \left[ \frac{R' R''}{1+\beta} p^2 + \frac{\dot{R}}{R^3} J^2 \right],
\]

\[
\frac{dp}{d\lambda} = 2\dot{R}' p \sqrt{\frac{1+\beta}{R} p^2 + \frac{2}{R^2}} + \frac{J^2}{R^3} R^2 + \frac{1+\beta}{R^3} R^2 p^2 + \left[ \frac{\beta'}{2 \beta + 2 \beta' - \frac{R'^2}{R^2}} \right] p^2.
\]

Following [3], the angle \( \xi \) along a geodesic is given by \( \cos \xi = -R'(t, r, p) / (u \sqrt{1+\beta(t, r, p)}) \), from which we obtain \( p_0 = -\sqrt{1+\beta(t_0, r_0)} \cos(\xi_0) / R'(t_0, r_0) \) and \( J_0 = J = R(t_0, r_0, \sin(\xi_0)) \). Therefore, our system is completely defined by the initial conditions \( t_0, r_0, \theta_0 = 0, z_0 = 0 \) and \( \xi_0 \). The first two define the instant of measurement and the offset between observer and center, while \( \xi_0 \) stands for the direction of incidence of the photons. By integrating the geodesic equations for two sources located at \((z_{a1}, z_{b1}, \xi_{a1}, \xi_{b1})\) after a time interval \( \Delta t \) the CP will be \( \Delta_{t,\gamma} = \gamma_2 - \gamma_1 = (\xi_{a2} - \xi_{b2}) - (\xi_{a1} - \xi_{b1}) \).

The models of Ref. [3] are characterized by a smooth transition between an inner void and an outer region with higher matter density and are described by the functions \( \alpha(r) \) and \( \beta(r) \) (Eqs. (28) and (29) in [3]), themselves carrying a total of 4 free parameters, one of which the value \( H_{\lambda,0} \) of the Hubble constant at the outer region, set at 51 km/(s Mpc). Following [3] we dub them Model I and II; the main difference between them is that Model II features a sharper transition from the void. However transition width is not expected to be an important factor in CP since most quasars are outside the void and the most relevant quantity is the difference between the inner and outer values of \( H \). In both cases we set the off-center (physical) distance to 15 Mpc, which is the upper limit allowed by CMB dipole distortions [3], and this corresponds to \( s \approx 4.4 \times 10^{-3} \) for a source at \( z = 1 \). It can be shown that in a step-like LTB void model, the \( H_X \) in [2] is given by \( H_{n,0}^{\mathrm{out}} X_{\nu_0}/X + H_{n,0}^{\mathrm{out}} (1 - X_{\nu_0}/X) \approx H_{n,0}^{\mathrm{out}} \), whereas \( H_{\mathrm{obs}} \approx H_{n,0}^{\mathrm{in}} \).

In Figure 2 we plot \( \Delta_{t,\gamma} \) for three sources at \( z = 1 \), for models I and II as well as for the FRW-like estimate. One can see that the results do not depend sensitively on the details of the shell transition and that in both cases the FRW-like estimate gives a reasonable idea of the true LTB behavior. We conclude that (2) is a valid approximation. Numerically, we find that a convenient estimate of the parallax is given by \( \Delta_{t,\gamma} = 100 s \Delta h/(\Delta t/10 \text{ years}) \times (\Delta \theta, \Delta z/\mu) \text{mas} \). For the LTB models above \( \Delta h \approx 0.12 - 0.14 \).

Integrating (7) yields also another interesting observable, \( \dot{z} = \Delta z/\Delta t \), coupled to the CP; together they form a new set of real-time cosmic observables. Ref. [13] calculated \( \dot{z} \) for an observer at the center of a LTB model. In the limit of small \( s \) our numerical results reveal that \( \dot{z} \) for off-center observers show very small angular dependence.

Cosmic parallax with Gaia. A realistic possibility of observing the CP is offered by the forthcoming Gaia mission. Gaia will produce in five years a full-sky map of roughly 500,000 quasars; by making of order 100 repeated measurements over the five years mission, Gaia will hopefully achieve a positional error \( p \) between 10 to 200 \( \mu \)as (for quasars with magnitude \( V = 15 \) to 20). To compare our observations to Gaia we need to evaluate the average \( \Delta_{t,\gamma} \) with \( \Delta t = 5 \) years and \( N \) sources. The final Gaia error \( p \) is obtained by best-fitting \( 2N \) independent coordinates from \( N^2/2 \) angular separation measures; the average positional error on the entire sky will scale therefore as \( (2N)^{-1/2} \). Over one hemisphere we can therefore estimate that the error scales as \( p/\sqrt{N} \). Since the average angular separation of random points on a sphere is \( \pi/2 \), the average of \( \Delta_{t,\gamma} \) can be estimated simply as \( \Delta_{t,\gamma}(\pi/2) \). We find numerically \( \Delta_{t,\gamma}(\pi/2) = 10 s \mu \)as, with little dependence on \( \Delta z \). Therefore Gaia can see the parallax if \( p/\sqrt{N} < 10 s \mu \)as. For \( s = 4.4 \times 10^{-3} \) (i.e. the current CMB limit) and \( p = 30 \mu \)as we need \( N \gtrsim 450,000 \) sources; this shows that Gaia can constrain the cosmic anisotropy to CMB levels. An enhanced Gaia mission with \( \Delta t = 10 \) years (or two missions 5 years apart), \( p = 10 s \mu \)as and \( N = 10^6 \) would give \( s < 5 \times 10^{-4} \), i.e. \( r_0 < 1 \text{ Mpc} \) if we assume the sources are at 2 Gpc. Two caveats of this preliminary estimate are however to be kept in mind. First, to map the angular change, Gaia’s observing strategy should be redesigned in order to maxi-
mize the time interval between quasar observations. Second, being planned to monitor the local matter distribution, Gaia’s errors estimates are based on using a fraction of the quasars as a reference frame. Observing the quasar CP would require a different statistical analysis. Both effects are likely to increase the expected final error.

Two local effects induce spurious parallaxes: one (of the order of 0.1 μas yr⁻¹) is induced by our own peculiar velocity and the other (of the order of 4 μas yr⁻¹) by a changing aberration. Both produce a dipolar signal, just like a LTB; however, the peculiar velocity parallax decreases monotonically with the angular diameter distance, while the aberration change is independent of distance [21]. In contrast, the LTB signal has a characteristic non-trivial dependence on redshift: for the models investigated here it is vanishingly small inside the void, large near the edge, decreasing at large distances. It is therefore possible in principle to subtract the cosmic signal from the local one, for instance estimating the local effects from sources inside the void, including Milky Way stars. A detailed calculation needs a careful simulation of experimental settings (including possibly effects like source photocenter jitter and relativistic light deflection by solar system bodies) which is outside the scope of this paper. Moreover, more general anisotropic models will not produce a simple dipole.

Conclusions. Planned space-based astrometric missions aim at accuracies of the order of few microseconds. In this paper we have shown that the cosmic parallax of distant sources in an LTB model might be observable employing the same missions. Similar considerations would apply to all other anisotropic cosmological models as e.g. the Bianchi models. A positive detection of large-scale CP would disprove therefore one of the basic tenets of modern cosmology, isotropy. We have shown that for a typical LTB model designed to explain the supernovae Ia Hubble diagram a enhanced Gaia experiment could constrain the anisotropy parameter s to less than 10⁻³, corresponding to the Megaparsec scale, much better than current CMB dipole limits [5]. Moreover, this test may probe a different range of scales depending on the quasar redshift distribution and, contrary to the CMB limits, the CP method cannot be completely undermined by the observer’s peculiar motion and is limited only by source statistics instead of by the cosmic variance. We anticipate however that the major source of systematics would be the subtraction of the aberration change parallax. Real-time cosmology tests directly cosmic kinematics by observing changes in source positions and velocities. We have shown that the cosmic parallax, along with the velocity shift effect z, can fully reconstruct the 3D cosmic flow of distant sources.
