BACKGROUND: Preterm birth is associated with the development of acute and chronic disease, potentially, through the disruption of normal gut microbiome development. Probiotics may correct for microbial imbalances and mitigate disease risk. Here, we used amplicon sequencing to characterise the gut microbiome of probiotic-treated premature infants. We aimed to identify and understand variation in bacterial gut flora from admission to discharge and in association with clinical variables.

METHODS: Infants born <32 weeks gestation and <1500 g, and who received probiotic treatment, were recruited in North Queensland Australia. Meconium and faecal samples were collected at admission and discharge. All samples underwent 16S rRNA short amplicon sequencing, and subsequently, a combination of univariate and multivariate analyses.

RESULTS: 71 admission and 63 discharge samples were collected. Univariate analyses showed significant changes in the gut flora from admission to discharge. Mixed-effects modelling showed significantly lower alpha diversity in infants diagnosed with either sepsis or retinopathy of prematurity (ROP) and those fed formula. In addition, chorioamnionitis, preeclampsia, sepsis, necrotising enterocolitis and ROP were also all associated with the differential abundance of several taxa.

CONCLUSIONS: The lower microbial diversity seen in infants with diagnosed disorders or formula-fed, as well as differing abundances of several taxa across multiple variables, highlights the role of the microbiome in the development of health and disease. This study supports the need for promoting healthy microbiome development in preterm neonates.

Pediatric Research (2022) 92:142–150; https://doi.org/10.1038/s41390-021-01738-6

IMPACT:

● Low diversity and differing taxonomic abundances in preterm gut microbiota demonstrated in formula-fed infants and those identified with postnatal conditions, as well as differences in taxonomy associated with preeclampsia and chorioamnionitis, reinforcing the association of the microbiome composition changes due to maternal and infant disease.
● The largest study exploring an association between the preterm infant microbiome and ROP.
● A novel association between the preterm infant gut microbiome and preeclampsia in a unique cohort of very-premature probiotic-supplemented infants.

INTRODUCTION

It is well known that preterm birth leads to retarded gut microbiome development and increased risk of acute and chronic disease in infants and adults.1 The gut microbiome composition of preterm infants differs significantly from those born full-term, and is characterised by lower diversity and high interindividual variation.2,3 In addition, despite high variability, preterm infants typically have fewer commensals like *Bifidobacterium*4,5 and *Lactobacillus*,4,6 and more potential pathogens like *Klebsiella pneumoniae*8 and *Clostridium difficile*.6 However, the gut microbiome is dynamic and changes significantly over time.9 Although reduced levels of common commensal organisms and diversity can persist for months,10,11 maybe years,12 choreographed abrupt changes in composition13,14 and increases in diversity11 mean that eventually the preterm gut microbiome composition becomes more similar to that of full-term infants.

Shifts in composition and organism dominance result from environmental changes and major colonising events. Colonisation occurs via different routes and is influenced by several factors, including delivery and diet. Delivery is the first major colonising
event, contributing significantly to differences between individuals, including higher abundances of vaginally derived microbes in those born vaginally. This includes Bacteroides and Lactobacillus. In contrast, caesarean-born infants acquire greater abundances of skin-dwelling microbes like Staphylococcus. As for diet, breastmilk and formula also produce distinct microbial communities due to the presence of both microbes and human-made oligosaccharides (HMOs) in breastmilk. Although maternal skin and vaginal microbes colonise infants during birth and feeding, these microbes may only be transient with maternal gut microbes, passed through birth or lactation proving to be more persistent.

As much of the microbial inoculation occurs through maternal–infant exchange, maternal health and medical interventions can also influence the developing infant microbiome. Interventions such as antibiotics and diseases like chorioamnionitis, a bacterial infection occurring before or during labour, have been previously shown to influence the infant microbiome. Thus, other maternal microbiome-altering diseases, like type 2 diabetes, preeclampsia, a pregnancy disorder characterised by high blood pressure, could also disrupt the infant microbiome. The resulting irregular infant microbiome could have severe consequences for infant health and development.

Disrupted microbial colonisation puts preterm infants at a high risk of acute infection, chronic disease, and developmental abnormalities. The increased risk of disease is a consequence of the breakdown in the symbiotic relationship between infants and colonising microbes, with delayed colonisation of commensal microbes contributing to an imbalance between normal flora and other microbes. In addition to this is an imbalance between commensals and pathogens that may induce intestinal inflammation and cytokine production. These microbial imbalances contribute to higher rates of acute diseases like necrotising enterocolitis (NEC) and sepsis, chronic diseases like asthma, and potentially, developmental disorders like retinopathy of prematurity (ROP).

This disproportionate burden of the disease leads to microbiome-altering treatment with antibiotics, a staple in preterm neonatal care and probiotics, an emerging preventative strategy. Antibiotics can disrupt microbial acquisition, resulting in reduced diversity and altered bacterial profiles, whilst probiotics have been shown to promote the growth of commensal microbes and increases in diversity, as well as reducing disease incidence.

As probiotic treatment is now common for the most premature of infants, this prospective observational study using 16S ribosomal RNA (rRNA) high-throughput analysis of faecal and meconium samples aimed to characterise the bacterial gut microbiome of probiotic preterm infants. Specifically, we set out to characterise changes in a probiotic-supplemented cohort of preterm infants from admission to discharge, and to examine the impact of several key variables on the microbiome. This includes assessing the reproducibility of past findings and exploring new potential associations through multivariable analyses.

**METHODS**

**Study population**

16S rRNA high-throughput sequencing was used to characterise the bacterial microbiome, down to genus, of infants receiving probiotic treatment and born into the Townsville Hospital and Health Service's Neonatal Intensive Care Unit (NICU). The THHS NICU is the only level six tertiary referral unit outside southeast Queensland, Australia. Thus, all babies being born at <29 gestation weeks in North Queensland (NQLD) are referred here. NQLD is affected disproportionately by preterm birth or lactation proving to be more persistent.

Decade, the burden that preterm birth places on NQLD families and the healthcare system is significant.

**Study design and ethics**

Ethics was obtained from the Human Research Ethics Committee from the THHS, and recruitment commenced in October of 2017 and continued until October of 2018. Inclusion criteria were infants born <32 weeks’ gestation and admitted to the NICU at the THHS. The exclusion criteria were no parental consent, gestational age of >32 weeks and contraindication to enteral feeds. One capsule of the probiotic Infoloran containing Lactobacillus acidophilus (1 × 10⁹ CFU) and Lactobacillus bifidus (Bifidobacterium bifidum) (1 × 10⁹ CFU), is administered via enteral feeds to all infants born <32 weeks gestations and <1500 g at the THHS NICU on a daily basis. Infoloran treatment is commenced on the first day of feeding and ceased once the infant is >34–36 weeks gestation.

Recruitment was conducted by a neonatal nurse/research assistant who works at the NICU, and sample collection was carried out by NICU nurses using collection kits (biohazard bag, sterile swab and storage container). Collection occurred at admission (meconium) and just prior to discharge (stool). After collection, samples were sent via a pneumatic tube system to Pathology Queensland and stored at −80 °C. Clinical information was also collected for descriptive analysis. This included both maternal data—antenatal antibiotics, antenatal infections (clinically diagnosed), chorioamnionitis (clinically diagnosed), prolonged membrane rupture (clinically diagnosed), preeclampsia (clinically diagnosed) and diabetes (type 1 or 2, self-reported), and infant data—sex, mode of delivery (vaginal birth versus Caesarean section), diet, gestation at birth and collection, NEC (stage 2 or greater), sepsis (confirmed through culture), days and timing of antibiotics, death, ROP (stage 1 or greater), birth weight, nursery discharge weight and date of birth. A summary of these data can be found in Table 1.

**Sequencing and bioinformatics**

In brief, the protocol used in this study included sample storage at −80 °C, an extraction kit that includes mechanical lysis, use of the Illumina MiSeq platform, targeting of the V3/V4 regions and use of the SILVA reference database.

DNA extraction was conducted using the Bioline ISOLATE Faecal DNA Kit, with modifications made in consultation with the manufacturer to optimise DNA yield. This included increased beta-mercaptoethanol (from 0.5 to 1% to increase DNA solubility and reduce secondary structure formation), the addition of an extra wash step (to improve purity) and decreased elution buffer volume (to increase final DNA concentration). For library preparation, we followed the Illumina metagenomics library preparation protocol, using the Index Kit v2 C, along with Platinum™ SuperFi™ PCR Master Mix. The MiSeq Reagent Kit V3 was used in combination with the Illumina MiSeq System, targeting the V3 and V4 regions with the S-D-Bact-0431-b-S-17/S-D-Bact-0785-a-A-21785F primer regions with the S-D-Bact-0431-b-S-17/S-D-Bact-0785-a-A-21785F primer.

Pre-analytical bioinformatics was conducted in R Studio Version 3.6.1, with a pipeline adapted from Workflow for Microbiome Data Analysis: from raw reads to community analyses, which along with the subsequent analyses can be found under Supplementary Material. DADA2 was used for quality filtering and trimming, demultiplexing, denoising and taxonomic assignment (with the SILVA Database), and the microDecon package was used to remove homogenous contamination from samples using six blanks originating in extraction.

**Statistical analysis**

Exploring changes in composition and diversity from admission to discharge. For statistical analysis, a phyloseq object was created using the package Phylatypes, with taxa filtered by prevalence (threshold = 0.01) and agglomerated at the genus level. The data were then explored through principal coordinate analysis (PCoA) plots using a Bray-Curtis dissimilarity matrix created from normalised (Total Sum Scaling) non-agglomerated data. Permutational analysis of variance (PERMANOVA) was then conducted for community-level comparisons between admission and discharge samples to observe group-level differences based on the Bray-Curtis dissimilarity matrix, using the adonis() function of the package Vegan. Alpha-diversity indices, Shannon index and Observed (richness) were then calculated on filtered, non-agglomerated data, and a comparison was made between admission and discharge samples using a Wilcoxon’s rank-sum test, with adjusted p values accounting for false discovery rate using the Benjamini-Hochberg procedure.
individual microbes whose abundance changed significantly from admission to discharge, data that were filtered and agglomerated at the genus level, but not transformed, were then normalised and modelled (negative binomial) with DESeq2. A Wald test with the Benjamini–Hochberg multiple inference correction was then performed to determine significant differentially abundant taxa.

Exploring the effect of clinical variables on alpha diversity and taxonomic abundance

Lastly, associations between several clinical variables and community structure were explored. The relationship between clinical variables and both Shannon diversity and taxonomic abundance was assessed using multivariate linear regression models. For exploring the relationship with Shannon diversity, a mixed-effects linear regression model was created using the package lme4 with a gaussian distribution and using the restricted maximum-likelihood estimation. Continuous predictors were assessed using the package multivariant linear regression models. For exploring the relationship with taxonomic abundance within samples (Observed and Shannon) increased from admission to discharge (Fig. 2c). Although there was a limited separation between the two groups (Fig. 2a, PERMANOVA; χ² = 2, d.f. = 0.06, homogeneity of variance; p = 0.85). The average species diversity within samples (Observed and Shannon) increased from admission to discharge (Fig. 2b), but not significantly.

Exploring the effect of clinical variables on alpha diversity and taxonomic abundance

Several maternal and infant variables were significantly associated with changes seen in the preterm infant gut microbiome. Mixed-effects models show that several clinical and environmental variables were significantly associated with both the diversity and taxonomic composition within samples. Significant pairwise differences in diversity were observed for diet, sepsis and ROP (Fig. 3), and chorioamnionitis, preeclampsia, sepsis, NEC, ROP and diet were all associated with changes in community (Table 2).

Mode of delivery and diet. Only diet had a significant impact on the gut microbiome, with the mode of delivery not reaching significance for alpha diversity (p = 0.057, Supplementary Material) or any taxa. The type of milk the infant received had a significant effect on alpha diversity (Fig. 3a; χ² = 13.5, df. = 2, p < 0.01), with subsequent post-hoc pairwise comparisons finding a significant difference between formula-fed infants (R = 2.10 ± 0.05) and breast milk-fed infants (R = 1.26 ± 0.06) and their respective formula-fed counterparts (R = 0.86 ± 0.05) and breast milk-fed counterparts (R = 0.95 ± 0.05) for the admission samples.

RESULTS

Exploring changes in composition and diversity from admission to discharge

The study recruited 85 preterm infants born <32 weeks and <1500 g from the THHS NICU. From these infants, 134 stool samples were collected, of which 71 were from admission (meconium) and 63 from discharge (stool). Other cohort demographics can be observed in Table 1. Significant changes in genera were observed between admission and discharge (Fig. 1), with Staphylococcus significantly higher at admission (p < 0.01), and Enterobacter (p < 0.01), Lactobacillus (p < 0.01), Clostridium sensu stricto 1 (p < 0.01) and Veillonella (p < 0.05) higher at discharge (Fig. 2c). Although there was a limited separation between admission and discharge samples, the beta diversity showed a clustering pattern that resulted in a significant difference between the two groups (Fig. 2a, PERMANOVA; p < 0.01 and R² = 0.06, homogeneity of variance; p = 0.85). The average species diversity within samples (Observed and Shannon) increased from admission to discharge (Fig. 2b), but not significantly.

For differential taxonomic abundance, two negative binomial generalised linear models were created using the package DESeq2. A combination of previous literature and exploratory analysis, including PCoA plots, PCA and scatterplots, were used for model selection. Again, continuous predictors were scaled and centered, and multicollinearity was assessed. Taxa were agglomerated at the genus level, due to the limited taxonomic depth of short amplicon sequencing. To reduce the number of false positives, two separate models were run; one each for admission and discharge samples. The resulting model assessed the effect of 11 independent predictors, sepsis, diet, chorioamnionitis, mode of delivery, gestation at birth, gestation at collection, NEC, preeclampsia, ROP and days on antibiotics prior to sample collection, on taxonomic abundance. Low abundance and low-frequency taxa were then removed, and a Wald test with the Benjamini–Hochberg multiple inference corrections was then performed. More information on the analysis can be found in the Supplementary Material.

Table 1. Overview of the demographic data for the cohort.

| Variables                  | Levels | Count | Percentage (%) |
|---------------------------|--------|-------|----------------|

| Weight at discharge       | 2448/2425 g |       |                |

NEC: necrotising enterocolitis, ROP: retinopathy of prematurity.
0.17) and those that were breastfed ($\chi^2 = 1.56 \pm 0.11$) (Fig. 3a; $p < 0.01$). For differential abundance, infants who were fed only breastmilk had significantly higher abundances of both *Bifidobacterium* (Table 2; $p < 0.05$) and *Klebsiella* (Table 2; $p < 0.05$), and lower *Veillonella* (Table 2; $p < 0.05$), relative to those that were only fed formula, but only at discharge. In addition, those fed only formula had significantly lower *Lactobacillus* at discharge (Table 2; $p < 0.01$).

**Pregnancy complications.** Both preeclampsia and chorioamnionitis had a significant impact on the infant gut microbiome, with both conditions significantly influencing taxonomy (Table 2). In infants whose mothers were diagnosed with chorioamnionitis before or during labour, *Staphylococcus* was significantly higher at admission (Table 2; $p < 0.05$). For infants whose mother was diagnosed with preeclampsia, there were no differences at admission (Table 2; $p < 0.05$) and *Klebsiella* was significantly lower at discharge (Table 2; $p < 0.001$) at discharge.

**Neonatal complications.** Three neonatal complications, ROP, NEC and sepsis, were found to significantly impact the developing preterm gut microbiome. Both sepsis (Fig. 3b; $\chi^2 = 4.70$, d.f. = 1, $p < 0.05$) and ROP (Fig. 3c; $\chi^2 = 10.98$, d.f. = 1, $p = <0.001$) significantly influenced diversity, with infants who were diagnosed with sepsis having significantly lower diversity ($\chi = 1.10 \pm 0.17$) than infants who did not have the disease ($\chi = 1.84 \pm 0.09$). For ROP, subsequent post-hoc analysis found pairwise differences at admission between infants who were diagnosed with the disease ($\chi = 1.25 \pm 0.18$) and those who did not have ROP ($\chi = 2.04 \pm 0.18$) (Fig. 3c; $p < 0.01$).

**DISCUSSION**

The aim of this study was to identify and understand variation in gut microflora development in a cohort of probiotic-treated preterm infants from North Queensland, Australia. Specifically, we set out to assess the difference in bacterial microbiome between two time points while the infant was in hospital admission and discharge. We also sought to understand the effect of several clinical variables (both maternal and infant) on the development of the gut microbiome. To do so, we utilised 16S rRNA gene high-throughput sequencing. We then conducted univariate comparisons to examine the difference between the infant microbiome at admission and discharge, and mixed-effects models to explore the influence of several clinical variables, including Sepsis, Feeding Type, Chorioamnionitis, Mode of Delivery, Gestation, NEC, Preeclampsia and ROP.

**Exploring changes in composition and diversity from admission to discharge**

Despite the overlap, the overall community structure was significantly different between admission and discharge faecal samples. *Staphylococcus*, commonly an early coloniser of the...
fewer or delayed colonisation of Lactobacillus oxygen-tolerant microbes like admission. In healthy newborns, colonisation usually begins with prematurity itself or supplementation with probiotics, which has the literature may be due to other confounding variables, such as skin-dwelling microbes. The inconsistency between our results and noteworthy.65,66 This is especially true considering their treatment across 99 samples in such a young cohort is also

Exploring the effect of clinical variables on alpha diversity and taxonomic abundance

Mode of delivery and diet. In contrast to previous studies, we observed no significant pairwise differences in diversity or taxonomy between vaginally and caesarean delivered infants at admission or discharge. Typically, caesarean-born infants bypass the vaginal route of inoculation, resulting in greater diversity, with fewer or delayed colonisation of Lactobacillus.15 Bifidobacterium10,15 and Bacteroides,67 coupled with higher than normal amounts of skin-dwelling microbes. The inconsistency between our results and the literature may be due to other confounding variables, such as prematurity itself or supplementation with probiotics, which has been demonstrated to alter Bifidobacterium and Lactobacillus populations in preterm infants. If probiotic treatment is driving the disparity between our results and previous work, this would support previous work suggesting probiotic supplementation can correct for microbial differences seen in caesarean-born infants.70

Regarding the influence of diet on the microbiome, we observed significantly lower alpha diversity and higher abundances of Bifidobacterium and Klebsiella at discharge in breastfed infants, relative to those solely formula-fed. The significant difference in Bifidobacterium supports previous work showing that breastfed infants have lower diversity in combination with more commensal microbes,15 including different Bifidobacterium species.15 The higher abundance of such microbes stems from the presence of both Bifidobacterium and HMOs in breastmilk.72-74 In addition, the higher abundance of Lactobacillus in infants who were fed a combination of formula and breastmilk, relative to those who only received formula, suggests that ‘supplementing’ formula feeding with some breastmilk may correct for some microbial imbalances associated with formula feeding. As for the differences in Klebsiella, the genus contains known pathogens such as Klebsiella pneumoniae, previously associated with NEC,75 and has been implicated in cases of sepsis. However, K. pneumoniae is a very diverse genus that is also part of normal flora.

Pregnancy complications. Maternal factors also significantly impacted the composition of the probiotic-treated preterm infant microbiome, with associations observed for both chorioamnionitis and preeclampsia. Infants whose mothers were diagnosed with chorioamnionitis had higher abundances of the genus Staphylococcus. Previous work has found microbes at different levels of taxonomy to be associated with chorioamnionitis, but not from...
the genus we observed. As chorioamnionitis is a bacterial infection of the placenta and membrane surrounding the foetus, occurring before or during labour, what pathogens are translocated from the membrane to the foetus may dictate the associations found. Unfortunately, the translocation and resulting increased abundance of Staphylococcus may be why exposure to chorioamnionitis increases the risk of preterm infants to adverse neonatal outcomes, like sepsis, which has previously been associated with Staphylococcus.

For infants whose mothers were diagnosed with preeclampsia, Escherichia/Shigella was significantly lower at discharge. As preeclampsia can alter the maternal microbiome, the resulting dysbiosis, at least in part, may be being passed through a maternal route of inoculation. Previous work by Stewart et al., The Environmental Determinants of Diabetes in the Young (TEDDY) study, has found that preeclampsia contributes to significant differences at the species, but not genus, level. However, the two cohorts are vastly different, with the TEDDY study including both full- and preterm children, with samples from 3 months of age. In contrast, our cohort was entirely preterm, who at discharge may have only been 3 months old. In addition, as preeclampsia is associated with preterm birth, our cohort had a larger proportion of infants born to preeclamptic mothers (18% compared to 4%). Taken together, preeclampsia may have a greater impact on preterm infants, or may have more of an effect in the early months of life, when the mother is still the dominant colonising route for microbes. As to why Preeclampsia only has an effect at discharge is unclear. However, as the impact is occurring via the maternal route, it may be related to continued exposure to the mother. This continued exposure through the maternal route of transmission, either by touch or breastmilk, may compound the passing of irregular taxonomic profiles that resulting from continued preeclampsia treatment post delivery.

Neonatal complications. We found that sepsis significantly influenced the abundance of Bifidobacterium, Pseudomonas and Enhydrobacter. Multi-omics approaches have previously linked sepsis to the gut microbiome, with other studies showing associations of sepsis with low diversity, as well as higher abundances of Staphylococcus, and lower abundances or absence of commensal microbes like Bifidobacterium. Although we also observed differences in Bifidobacterium, the directional effect is counter to what was observed previously. However, it is worth noting that of the eight infants diagnosed with sepsis, only three had Bifidobacterium in their sample. So, despite reaching statistical significance, this finding may not be clinically relevant.

For NEC, we observed significantly lower abundances of Bifidobacterium, but in contrast to previous work, no enrichment of any taxa. As previously mentioned, Bifidobacterium is a common commensal microbe found in the probiotic Infloran®, which is uncommon in preterm infants born <33 weeks gestation and has previously been shown to be protective against NEC. Although our work does not support previous evidence of an associated pathogen, the plethora of microbes that have previously been associated with NEC, in combination with studies showing reduced commensal microbes and diversity, suggests the aetiology is more complex than just the presence of a pathogen.

We also observed significant enrichment of Staphylococcus (of the Staphylococcaceae family) and lower diversity at admission for infants diagnosed with ROP. An association between the gut

microbiota and ROP has been explored once before, by Skondra et al. They observed significant enrichment of the family Enterobacteriaceae in preterm infants with the disease at 28 weeks postmenstrual age. The discrepancy in our results is not necessarily a product of error, but rather, as seen with NEC, due to the complex aetiology characterised by more than just the presence of a particular group of taxa. This complexity makes it difficult to hypothesise the specific role that the microbiome could be playing in ROP. However, if a role is established there is potential for the microbiome to become a target for intervention, and thus this should be the target of further research.

Limitations of our work include low taxonomic depth and only sampling in early infancy. The use of 16S rRNA gene metabarcode- ing limited detection power to the genus level, resulting in no identification of species or functional genes. In addition, collecting samples only at admission and discharge means we have no insight into the longevity of the differences observed; this may impact the clinical significance. Future work will use a combination of 16S rRNA gene metabarcodeing and shotgun metagenomic techniques to both characterise species allowing an exploration of the differences observed in this study and others, and to investigate if these persist in the long term.

This prospective observational study used 16S rRNA gene sequencing to characterise the bacterial microbiome of probiotic-supplemented infants. The study aimed to identify and understand variation in bacterial gut flora between two time points and as the result of several clinical variables. Our study builds on previous research and supports other studies describing significant changes in the preterm microbiome over time and associations with several factors. The lower bacterial diversity seen in infants diagnosed with diseases or who were formula-fed, as well as the differing abundances of several taxa across multiple variables, reinforces the role of the microbiome in disease and supports the need for promoting healthy microbiome development. In addition, the associations with maternal disease highlight the importance of maternal health to infant microbiome development, and in turn infant health.

### Table 2. The significant differentially abundant taxa at the genus level obtained from DESeq2 analysis, with log 2 fold change for the variable listed compared to the base value.

| Log 2 fold change | lfcSE | p_adj | Genus | Variable | Sample |
|-------------------|-------|-------|-------|----------|--------|
| 3.09              | 0.99  | *     | Staphylococcus | Chorioamnionitis: yes | Admission |
| −17.58            | 3.22  | ***   | Enhydrobacter | Sepsis: yes | Admission |
| −15.38            | 3.95  | **    | Pseudomonas | Sepsis: yes | Admission |
| 10.33             | 2.84  | **    | Bifidobacterium | Sepsis: yes | Admission |
| −11.62            | 2.31  | ***   | Bifidobacterium | NEC: yes | Admission |
| 4.84              | 1.00  | ***   | Staphylococcus | ROP: yes | Admission |
| −27.65            | 2.64  | ***   | Escherichia/Shigella | Preeclampsia: yes | Discharge |
| −4.25             | 1.67  | *     | Veillonella | Diet: breastmilk | Discharge |
| 2.54              | 0.87  | *     | Bifidobacterium | Diet: breastmilk | Discharge |
| 3.64              | 1.46  | *     | Klebsiella | Diet: breastmilk | Discharge |
| −5.52             | 1.91  | *     | Lactobacillus | Diet: formula | Discharge |

p_adj adjusted p value, lfc log-fold change, lfcSE log-fold change standard error, NEC necrotising enterocolitis, ROP retinopathy of prematurity.

*P < 0.05, **P < 0.01 and ***P < 0.001.

ACKNOWLEDGEMENTS
We thank Helena McInnes, Nicole Dionysius, Dr. Tiffany Kosch, Harrison Jaa-Kwee and Sandra I. Villamil.

AUTHOR CONTRIBUTIONS
Substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data: J.A.F.W., D.R., Y.K., R.H., R.N., K.M.S. and D.W. Drafting the article or revising it critically for important intellectual content: J.A.F.W., D.R., C.M.M., Y.K., R.H., R.N. and K.M.S. Final approval of the version to be published: D.R., C.M.M., Y.K., R.H., R.N., K.M.S., J.A.F.W. and D.W.

FUNDING
This work was funded through the Townsville Hospital and Health Service with a Study, Education and Research Trust Account (SERTA) research grant. The funding body had no role in the design of the study or collection, nor the interpretation of data and writing.

COMPETING INTERESTS
The authors declare no competing interests.

ETHICS APPROVAL AND CONSENT TO PARTICIPATE
The research was performed in accordance with the Declaration of Helsinki and ethics approval was obtained from the Human Research Ethics Committee from the Townsville Hospital and Health Service (HREC/17/QTHS/7). Informed consent was obtained from parents/legal guardians of all subjects through the signing of a Parental Information Sheet and Consent Form (PICF).

ADDITIONAL INFORMATION
Correspondence and requests for materials should be addressed to Jacob A. F. Westaway.
