Abstract

The mechanisms of coral calcification at the molecular, cellular and tissue levels are poorly understood. In this study, we examine calcium carbonate precipitation using novel coral tissue cultures that aggregate to form "proto-polyps". Our goal is to establish an experimental system in which calcification is facilitated at the cellular level, while simultaneously allowing in vitro manipulations of the calcifying fluid. This novel coral culturing technique enables us to study the mechanisms of biomineralization and their implications for geochemical proxies. Viable cell cultures of the hermatypic, zooxanthellate coral, Stylophora pistillata, have been maintained for 6 to 8 weeks. Using an enriched seawater medium with aragonite saturation state similar to open ocean surface waters ($\Delta_{\text{arag}} \approx 4$), the primary cell cultures assemble into "proto-polyps" which form an extracellular organic matrix (ECM) and precipitate aragonite crystals. These extracellular aragonite crystals, about 10 $\mu$m in length, are formed on the external face of the proto-polyps and are identified by their distinctive elongated crystallography and X-ray diffraction pattern. The precipitation of aragonite is independent of photosynthesis by the zooxanthellae, and does not occur in control experiments lacking coral cells or when the coral cells are poisoned with sodium azide. Our results demonstrate that proto-polyps, aggregated from primary coral tissue culture, function (from a biomineralization perspective) similarly to whole corals. This approach provides a novel tool for investigating the biophysical mechanism of calcification in these organisms.

Introduction

The potential effects of global warming and ocean acidification on coral calcification have received significant attention in recent years [1–2]. However, despite the broad interest in coral calcification [3–6] and the potential for climate-driven adverse effects, the actual calcification mechanisms are still poorly understood at the cellular level. A lack of mechanistic understanding of processes that lead to and control calcification limits our ability to predict corals' response to increasing atmospheric CO$_2$ [6]. Thus, if we are to truly predict the effects of increasing atmospheric pCO$_2$, it is of critical importance to understand these mechanisms. This will also provide a stronger basis for interpreting geochemical proxies in corals.

Corals (phylum, Cnidaria) belong to one of the oldest invertebrate phyla. They are the earliest metazoaans that possess an organized body structure. Their body plan consists of two cell layers: an ectoderm and an endoderm, separated by the mesoglea, which is a non-cellular gelatinous matrix [7]. In symbiotic corals, the endoderm hosts unicellular algae of the genus *Symbiodinium*. These tissues are mechanically anchored to the skeleton by desmocytes [8]. The aboral ectoderm in contact with the skeleton, referred to as the calcisclerotic epithelium, is involved in the extracellular production of the aragonite (orthorhombic CaCO$_3$) coral skeleton under its apical membrane [9]. The sub-calcioblastic space between the skeleton and the calcisclerotic epithelium, containing the "calcifying fluid" in which new skeletal material is precipitated, does not exceed a few nanometers [3]. Accessing this extremely small space is very difficult and prevents detailed physiological studies of sub-calcioblastic chemical variability. The lack of mechanistic understanding of the calcification process also constrains our ability to interpret geochemical proxies in corals (e.g., $\delta^{13}$B for reconstructing seawater pH) using calibrations based solely on correlative geochemical signatures of intact living corals [10–12].

Previous studies that attempted to quantify the in vivo chemistry at the cellular level rely on microsensor pH measurements within the calcifying fluid or fluorescent dyes that give information about pH and/or calcium concentrations [13,14]. Using microelectrodes, Al-Horani et al. [10] found, in the coral *Galaxea fascicularis*, large shifts in pH from 9.3 to 7.5 under light and dark conditions, respectively. Similarly, higher pH in the calcifying fluid than in the ambient seawater was reported in the coral *Stylophora pistillata* based on a pH-sensitive fluorescent probe (SNARF-1) [14]. The diurnal pH shift reported in the latter study was lower under comparable light and dark conditions (from $\sim$8.7 to $\sim$8.4). However, given that these two studies were conducted on different coral species and with different methodologies, identical pH values...
Materials and Methods

Cell Cultures

Coral fragments from the zooxanthellate coral, *Stylophora pistillata*, were obtained from nubbins growing in an 800 L, custom-designed aquarium as described previously [21]. Cell cultures were prepared following previously published procedures, with small modifications [20]. Briefly, small fragments of coral were excised from parent colonies and incubated for 3 to 5 h with gentle shaking in calcium-free artificial seawater supplemented with a 3% antibiotics-antimycotics and 20 μg mL⁻¹ chloramphenicol solution (GIBCO). Fragments were then transferred to 35×10 mm Primaria culture dishes containing 3 mL of culture medium. The medium was prepared in two steps:

- Dulbecco’s Modified Eagle Medium (DMEM) with no glucose (Invitrogen) supplemented with the following major seawater ions: 0.35 g l⁻¹ KCl, 1.1 g l⁻¹ CaCl₂, 1 g l⁻¹ MgSO₄, 7H₂O, 18.1 g l⁻¹ NaCl, 0.052 g l⁻¹ taurine and 25 mM HEPES buffer [22].
- A mixture of artificial seawater (Instant Ocean sea salt, Aquarium Systems 34 p.s.u.), 12.5% modified DMEM (from step 1), 20 μg/mL aspartic acid, 2% heat-inactivated FBS (Invitrogen), 1% antibiotic–antimycotics solution (GIBCO), 0.1 μM glucose, and 50 μg mL⁻¹ L-ascorbic acid.

Cultures were exposed to the same atmospheric conditions as in the aquarium. Therefore, in order to avoid evaporation of the medium and to keep the growth conditions similar to that in the aquarium, the cultures were maintained in an environmental growth chamber (Percival scientific, INC, USA) on a 12:12 h light:dark cycle at 26°C and 80% humidity, and the media was replaced every 7 days. The carbonate alkalinity of the final medium solution (without the HEPES buffer) was 2215 μmol kg⁻¹, as measured by Gran titration [23]. We note that within the analytical error of the method the titration of the artificial seawater only yielded similar carbonate alkalinity to that determined on whole media, suggesting a minimal effect of the organic components. The pH of the medium was maintained at 8.0±0.1 by the HEPES buffer. We calculated Ω_{aragonite} to be 3.7 using an online program that calculates in situ CO₂ conditions [24]. These conditions mimic open ocean surface waters and the carbonate saturation state in our aquaria. After 48 h, the coral skeleton was removed from the plate, and the medium with the detached cells was centrifuged (8500× g for 10 min). The pellet was re-suspended in fresh media and filtered through 20 μm nylon mesh to remove cell aggregates and debris. In order to rule out the possibility that observed aragonite crystals were formed by inorganic precipitation in the saturated culture medium the following controls were set: (1) a plate with medium but no culture cells; and (2) a primary cell culture treated with 15 mM sodium azide, that through respiratory inhibition, prevents reduction of O₂ to water by the heme co-factor of cytochrome oxidase in mitochondria.

Chlorophyll a concentrations were measured by the method of Jeffrey and Humphrey [22] on a DW2000 spectrophotometer after culture samples had been extracted in 90% acetone overnight at −20°C. A rapid assessment of photosynthetic activity of zooxanthellae was determined by use of a Fluorescence Induction and Relaxation (FIRE) fluorometer [25,26].

Microscopy Imaging

Microscopy imaging was carried out with an inverted IX71 epifluorescent microscope (Olympus) and a Zeiss LSM 710 confocal microscope. For confocal images, cells were grown on glass bottom dishes (WillCo-Dish). Excitation wavelengths at 490, 488 nm with emission wavelengths at 510, 667 nm were used for green fluorescence proteins (GFP) and chlorophyll fluorescence measurements, respectively.

For field emission scanning electron microscopy (FE-SEM) and energy-dispersive X-ray spectrometry (EDS), cells were grown on Millipore cell culture inserts in 6-well tissue culture plates (Millipore). These cultures were fixed for 2 h with 2% glutaraldehyde in 0.05 M phosphate buffer (pH 7). Some of the samples were gently washed with distilled water and the rest were...
incubated in 1 M NaOH at 90°C for 20 minutes to denature cellular membranes, followed by dehydration with an ascending ethanol series (50–100%) and critical point drying with liquid CO₂. All samples were then coated with gold and platinum and observed on a Zeiss Sigma FE-SEM equipped with Gemini column and Oxford Instruments with an IncaPenta FET-X3 detector.

**DNA Extraction PCR Amplification and Sequencing**

Total genomic DNA of the cell culture was extracted from harvested cells using a blood and cell culture DNA mini kit (Qiagen # 13323). *S. pistillata* mitochondrial 16S rDNA and cytochrome oxidase subunit I (COI) were amplified using the primers LCOant 5'-TTT ACT CAT AAA GAT AT-3' and COIantr 5'-GCC CAC ACA ATA AAG CCC AAT AYY CCA AT-3' [27]. *Symbiodinium* sp. 18S rDNA was amplified using the algae-specific primers ss5z (an equimolar mixture of 5'-GCC AGTATAATTTATTTGATGGTCACTGCTAC-3' and 5'-CAGTCCGAATAATTCACCGG-3') and the complementary primer ss3z (5'-AGCACTGCGT-CAGCTCGAATAATTACCGG-3') [16].

All PCR reactions contained 0.1–0.4 µg of template DNA, 10 mM total dNTP, 1 x REDTaq reaction buffer, 0.1–0.5 µM of each primer and 0.05 unit µL⁻¹ of REDTaq polymerase (sigma #D4309) in a total volume of 25–50 µL. Amplifications were performed using a Perkin Elmer-Cetus 480 Thermal cycler with the following thermal profile for the *S. pistillata* and algae-specific primers respectively: 40 cycles of 30 sec at 94°C, 30 sec at 40°C, 90 sec at 72°C, and 30 cycles of 1 min at 94°C, 2 min at 55°C, 3 min at 72°C. PCR products were cloned using the TOPO TA cloning kit (Invitrogen) and transformed into *Escherichia coli* (Top10). Plasmids were purified by the QIAprep spin miniprep kit (Qiagen) and sequenced by Genwiz sequencing service (http://www.genewiz.com/).

**Characterization of CaCO₃ and ECM**

Aragonite mineralogy was confirmed for 7–10 days old culture by X-ray diffraction (XRD) on a Bruker/Siemens Hi-Star detector. Contents of 5–10 wells of each treatment (see above) were scraped with a rubber policeman, combined, and centrifuged. The pellet was rinsed with Milli-Q deionized water and then resuspended in 1 M NaOH and heated to 90°C for one hour. Samples were again centrifuged and the NaOH-insoluble pellet was rinsed with Milli-Q water, dried at 60°C, and stored until analysis. Additionally, skeleton samples of the mother colony were bleached in 1% commercial bleach at room temperature for 4 h, rinsed extensively, dried, and ground to a fine powder with mortar and pestle made of agate. The powder was soaked again for 4 hours in 1% bleach, rinsed extensively, and dried. Samples were mounted onto borosilicate capillary tubes and analyzed by XRD. We added <1 mg LaB₆ (NIST SRM-660a), a calibration standard, to the culture samples to confirm accuracy of peak identification; this is common for very small samples (i.e.; <1% of the aragonite mass used in mother colony skeleton analyses). Resulting spectra were processed in GADDS software (Bruker AXS).

Amino acid composition of ECM proteins was determined by high performance liquid chromatography (HPLC) after acid hydrolysis of proteins extracted from decalcified skeletons of *S. pistillata* and from NaOH-insoluble culture ECM. Briefly, skeletons were cleaned as described above for XRD, then subsamples of clean skeleton powder and NaOH-treated culture pellet were decalcified in 1N HCl for four hours. The solutions were neutralized and water-soluble and insoluble proteins were separated by centrifugation. Soluble proteins in the supernatant were concentrated by centrifugal filtration (3500× g) on Amicon Ultra filters (Millipore, 3 kDa cut-off), and both solubility fractions were then lyophilized. Dried organic matrix samples were hydrolyzed in 6 N hydrochloric acid at 110°C for 18 hours and then neutralized with NaOH. Subsamples were analyzed according to the modified methods of Mopper and Lindroth [28]. Hydrolyzed amino acids were combined with o-phthalidialdehyde/N-acetyl-L-cysteine in 0.8 M borate buffer (1:3) and allowed to react at room temperature for 2 min. The derivatization solution was run on a Shimadzu HPLC fitted with an ODS Rexchrom column (Regis, 5 µm) and sodium acetate/methanol mobile phase.

**Figure 1. Relief contrast images of coral cell cultures.** (A) Relief contrast of individual cells in *Stylophora pistillata* primary cell culture at 72 h. (B) 40 h (C) 50 h and (D) 73 h in culture (magnification 20×).

**Figure 2. Relief contrast, confocal and SEM images of proto-polyp.** (A) 72 h old proto-polyp (magnification 40×). (B) Z-stack of a proto-polyp at 12 d. The *Symbiodinium* sp. cells are seen by chlorophyll florescence and animal cells are revealed by GFP fluorescence. (C) SEM of 12 d old proto-polyp cell organization, and (D) extracellular precipitation of aragonite crystals associated with proto-polyp.
Results and Discussion

Self-assembly of proto-polyps

Within 2 days of culture initiation, *S. pistillata* tissue, which had been pre-incubated for 3 to 5 h in calcium-free seawater, spontaneously dissociated from the skeleton into separate, discrete cells. Dissociated cells consisting of a mixture of cell types including free *Symbiodinium* sp. and individual endoderm and ectoderm cells (Fig. 1A), were placed in the culture dish. These cells do not appear to morphologically dedifferentiate (*i.e.*, they do not form stem cells), however, transferring the coral fragment to the culture medium suppressed photosynthetic activity in the *Symbiodinium* sp. After 24 hours, photosynthetic efficiency, measured as $F_v/F_m$, was undeterminable compared with intact coral fragments (~0.50). It should be noted, however, that the chlorophyll concentration did not change during this time period.

Figure 3. SEM images and elemental composition. SEM images of typical columnar aggregates of aragonite crystals, elongated along the c axis, formed in the dorsal surface of the cell culture (A–B) and in the *S. pistillata* skeleton (C). In both aggregates one can see the orthorhombic structure, characteristic of aragonite crystals. (D) ECM of a proto-polyp after cells removed by 1 M NaOH. Red circle on the SEM image indicates the sample point of the EDS. Energy-dispersive X-ray spectrum showing calcium carbonate composition of the aragonite crystal in (a) proto-polyp, in (c) coral skeleton and (d) in the ECM scaffold while (b) the composition in the cells is C, O, N and P. The Au and Pd peaks are from the gold coating. doi:10.1371/journal.pone.0035049.g003
Figure 4. Aragonite mineralogy. X-ray powder diffraction pattern of (A) tissue culture sample and (B) of a powdered mother colony skeleton showing the characteristic diffraction peaks of aragonite. Composite minerals were determined by peak matching of XRD data in Jade software (MDI Products, Inc.). Peaks at 26.3 and 45.9 degree are characteristic aragonite peaks. Peaks at 21.6, 30.4, 37.4, 43.5, 49, and 54 degrees are due to LaB₆, added to ensure correct peak identification of very small samples (C).

The observed inhibition of photosynthesis could have been the result of the glucose added to the culture medium that was utilized as an exogenous organic substrate (in lieu of photosynthetic fixation) and subsequently respired by the *Symbiodinium* sp. [20,29].

The presence of coral cells and *Symbiodinium* sp. in the cultures was confirmed by polymerase chain reaction (PCR) using anthozoan- and *Symbiodinium*-specific primers and blasting the PCR-derived sequences against the National Center for Biotechnology Information nucleotide database (www.ncbi.nlm.nih.gov) (Fig. S1).

Within 48 h, individual cells in the culture assembled into organized cell clusters, consisting of 3 layers (Fig. 1B-D, Figs. S2, S3). The viability of these “proto-polyps” remained >80% over a period of ~5 weeks, as was quantitatively assessed by using Sytox green [20], after which microbial contamination became unavoidable. Therefore, all calcification and metabolic measurements were preformed on 5 to 10 day-old uncontaminated cultures. Cells adhered to the Primaria dish substratum through ECM that mediated cell-cell, as well as cell-substratum adhesion. In addition, assembly of larger spherical aggregations ~80 μm thick, which detached from the substratum, was observed (Fig. 2A). Cell cultures treated with 15 mM sodium azide did not aggregate, ruling out the possibility of spontaneous aggregation.

Aggregates incorporated all individual cell types (ectoderm or endoderm cells, *Symbiodinium* sp., and nematocysts). *Symbiodinium* sp. cells, as indicated by chlorophyll fluorescence, were located in the middle part of the aggregation (20–50 μm). In contrast, animal cells, as indicated by GFP fluorescence, were located throughout the aggregate (Fig. 2B, S3). Associated with all aggregates, we observed the formation of aragonite crystals (Fig. 2D).

**Aragonite precipitation**

Relatively large, extracellular crystals were detected after 10 days in cell culture, on the surfaces of both adherent and non-adherent *proto-polyps* (Fig. 3A). Crystal growth was not observed on individual cells. Crystals on *proto-polyps* formed distinct flower-shaped bundles, originating from the upper surface facing the media, and were attached to ECM (Fig. 3A). Once the animal's cells were removed from the *proto-polyp* by 1 M NaOH, the structure of the ECM was revealed (Fig. 3D). In contrast, no calcium carbonate crystals were detected by XRD or EDS in the control treatments, treatments made of culture medium without cells, or with addition of 15 mM sodium azide to healthy cultures.

The elongated shape and morphology of crystals are similar to aragonite crystals observed in the septa of the *S. pistillata* mother colony (Fig. 3C), which are one of the primary sites of CaCO₃ precipitation [30]. Indeed, XRD analysis of these crystals confirmed that the calcium carbonate polymorph precipitated in our healthy coral cell cultures was aragonite (Fig. 4). Aragonite crystals formed in cell cultures were about 10 μm long. In comparison, aragonite crystals from the mother colony of *S. pistillata*, growing in the in-house aquarium, were smaller than those produced *in vitro* despite the similarity in saturation levels (Fig. 3). Previous studies describe similar morphology and orientation for aragonite crystals at active growing regions of corals as those observed in our tissue cultures [31,32].

Chemical analysis by energy-dispersive X-ray spectroscopy (EDS) confirmed that crystals observed were, indeed, calcium carbonate. A typical X-ray spectrum of a crystal in the *proto-polyp*, the mother colony skeleton and of the ECM reveals a prominent calcium peak (Fig. 3). In addition to the calcium peak, a second prominent sulfur peak can be seen in the crystal deposit in the *proto-polyp* (Fig. 3a). However, sulfur peaks were not observed on the cell section of the *proto-polyp* (Fig. 3b), but rather peaks corresponding to nitrogen, carbon and oxygen that are associated with the organic matrix were detected. As the initial crystals emerged from the ECM, the sulfur peak observed in those crystals, and not in the mother colony skeleton, may result from relatively abundant sulfate-bearing organic compounds at centers of calcification but lower organic matter concentrations in the bulk skeleton, as suggested by Cuif et al. [33]. These results support the Cuif et al. [33] proposed model of crystal growth that involves a step-by-step growth of aragonite fibers where each step is initiated and guided by a sulfated organic matrix sheet.

**ECM composition**

The total ECM was separated by centrifugation into soluble and insoluble fractions. Total aspartic acid plus asparagine content (Ass), measured by HPLC, was ~20% of total ECM skeletal protein content for both fractions. The second most abundant amino acid was glutamic acid plus glutamine (Glx), also accounting for ~20% of the total. Thus, these two sets of amino acids account for ~40% of the total in both soluble and insoluble ECM fractions both in the mother colony and cell culture ECM (Table 1). Similar to our study, Young [15] reported 12–23% of
Asx in skeletons from 14 different species of scleractinian corals. Specific functions of the soluble and insoluble ECM fractions in the calcification processes have yet to be determined. While some differences have been found between the two fractions, many similarities have been indicated, including polar amino acid content and protein size and activity [34,35]. Differences between the two fractions may be ascribed to their roles in either structural framework (insoluble ECM) or crystal nucleation (soluble ECM) [36–38]. However, as only one ECM protein has been fully sequenced, the distinctive and/or overlapping nature of soluble and insoluble ECM proteins remains to be seen [39].

Sulfur has been shown to be integral to centers of calcification in coral skeletons [33]. We have confirmed a lower amount of sulfur containing material in ECM compared to primary crystals by EDS (Fig. 3). In addition, we measured 0.5–1% methionine residues in *S. pistillata* mother colonies by HLPC (this method does not allow quantification of cysteine).

### Final Remarks

In this study we demonstrate that a primary culture of disaggregated coral cells can re-assemble into *proto-polyps* from primary, differentiated cells. Each *proto-polyp* contains three cell layers organization.

Sulfur has been shown to be integral to centers of calcification in coral skeletons [33]. We have confirmed a lower amount of sulfur containing material in ECM compared to primary crystals by EDS (Fig. 3). In addition, we measured 0.5–1% methionine residues in *S. pistillata* mother colonies by HLPC (this method does not allow quantification of cysteine).

### Table 1. Relative amino acid composition of skeletal and cell culture ECM as determined by HPLC fluorometric analysis.

| Amino Acid                     | Skeleton (Soluble) | Skeleton (Insoluble) | Cell Culture (Soluble) | Cell Culture (Insoluble) |
|--------------------------------|--------------------|----------------------|------------------------|--------------------------|
| Asparagine or aspartic acid (Asx) | 19                 | 21                   | 20                     | 27                       |
| Glutamic acid or glutamine (Glx) | 15                 | 18                   | 21                     | 19                       |
| Serine                         | 9                  | 10                   | 3                      | 4                        |
| Threonine                      | 20                 | 11                   | 2                      | 1                        |
| Glycine                        | 18                 | 14                   | 15                     | 10                       |
| Histidine                      | 5                  | <1                   | <1                     | <1                       |
| Arginine+Alanin                | 5                  | 6                    | 8                      | 8                        |
| Tyrosine                       | <1                | 2                    | 2                     | <1                       |
| Valine                         | 3                  | 8                    | 6                      | 8                        |
| Methionine                     | 1                  | <1                   | 2                      | 2                        |
| Phenylalanine+Isoleucine       | 2                  | 6                    | 8                      | 8                        |
| Leucine                        | 3                  | 4                    | 13                     | 13                       |
| Total                          | 100               | 100                  | 100                    | 100                      |

Cell culture ECM is derived from the NaOH-treated pellet.

layers; a basal layer of ectodermal cells that adheres to the plate is covered with a second layer of endodermal cells containing zooxanthellae (Fig. 5). The top layer contains ectodermal calciclastic cells exposed directly to medium. In coral colonies aragonite is precipitated on ECM scaffolding that is secreted into the calicoblastic space by ectodermal cells facing the skeleton [2]. In contrast, in our culture the calicoblastic layer is exposed to the artificial calciclastic fluid surrounding the proto-polyp (Fig. 5).

Under these culture conditions, we propose that the calciclastic cell layer secretes ECM with sulfate rich calcifying centers [33] onto which the aragonite crystals precipitate (Fig. 3). We note that the ECM amino-acid composition produced by the cell culture is similar to that of the mother colony. Aragonite crystals in cell cultures have similar structure and chemical composition to the mother coral colony skeleton; however, they are substantially larger than those in the mother coral (10 μm vs. 2 μm, respectively). The difference is likely due to the fact that in the culture the new skeleton formation is not constricted by the small calciclastic space as it is inside a coral colony, therefore crystals extend to greater lengths and are lower in density (Fig. 3). Regardless of morphological differences, however, our results clearly suggest that coral cells can catalyze carbonate crystal formation under ambient concentrations of DIC. How that process occurs remains fundamentally unknown. This study demonstrates the potential of coral cell culture for studying physiological mechanisms, including calcification and cell differentiation, at the cellular level. This will provide a critical tool for mechanistically understanding how shifts in ocean pH will impact calcifying corals.

Supporting Information

Figure S1 DNA partial sequence. S. pistillata mitochondrion sequence (Upper) and 18S rDNA of Symbiodinium sp. (Lower) (PDF)

Figure S2 Relief contrast video of coral cell cultures. Link to a movie of proto-polyp assembly after 72 h in culture medium.

Figure S3 Frame by frame confocal imaging: Frame every 2 μm of Z-stack of a proto-polyp at 12 d. The Symbiodinium sp. cells are seen by chlorophyll fluorescence located in the middle of the aggregation (20–50 μm) while animal cells are revealed by GFP fluorescence located in the whole aggregate.

Acknowledgments
We thank F. Natale, T. Emge, M. Gorbonov; Y. Helman, S. Miller, I. Heifetz, K. Wyman and V. Starovoytov for advice and analytical assistance. We also thank J. Yailillo from the Long Island Aquarium and Exhibition Center for donating corals for this research.
