(Dated: April 25, 2019)

We consider the interaction of two weak probe fields of light with an atomic ensemble coherently driven by two pairs of standing wave laser fields in a tripod-type linkage scheme. The system is shown to exhibit a Dirac-like spectrum for light-matter quasi-particles with multiple dark-states, termed spinor slow-light polaritons (SSP). They possess an "effective speed of light" given by the group-velocity of slow-light, and can be made massive by inducing a small two-photon detuning. Control of the two-photon detuning can be used to locally vary the mass including a sign flip. This allows e.g. the implementation of the random-mass Dirac model for which localized zero-energy (mid-gap) states exist with unusual long-range correlations.

PACS numbers: 42.50.Ct, 03.65.Pm, 71.23.An

Due to the recent experimental and theoretical progress on various system there has been a growing interest in interacting systems with effective single-particle Dirac dynamics. A prime example is Graphene [1] which shows unusual low-energy properties, described by Dirac quasi-particles. The effective “speed of light” of these quasi-particles is given by the electron Fermi velocity, which is about 300 times smaller than the vacuum speed of light. We here show that an effective Dirac-like dynamics also emerges for two-component, i.e. spinor-like, slow-light polaritons [2] in 1D. They possess a controllable effective speed, corresponding to the much smaller group velocity of light [3] in media exhibiting electromagnetically induced transparency (EIT)[2]. This may allow experimental studies of a number of interesting effects of relativistic dynamics at low energies and small velocities. Additionally the effective mass, determined by laser detuning, is locally and dynamically adjustable including the sign, which provides access to interesting phenomena such as the unusual localization in a Dirac model where the mass is a random function of space [4, 5]. The latter is inaccessible for truly massive particles such as cold atoms.

Slow-light polaritons are formed in the Raman interaction of a weak probe field with a coherently driven ensemble of atoms with a Λ-type linkage pattern (Fig. 1a). They build the basis of ultra slow light [3], light storage [6, 7] and, upon using two counter-propagating control fields (Fig.1b,c), stationary light [8–10]. They exhibit extraordinary long lifetimes ranging from several hundreds of microseconds[6] up to hundreds of millisecond [11, 12] and offer a wide range of tuning parameters.

In the following we argue that by adding additional states to the above linkage pattern (Fig.1d), we can create a spinor-like object consisting of two adiabatic eigen-solutions immune to spontaneous decay. The suggested tripod linkage interaction between atoms and lights is a minimal realization of spinor slow-light polaritons (SSP). They obey an effective 1D Dirac equation, thus creating relativistic quasi-particles with an internal degree of freedom. They travel at an effective speed c* given by the slow-light group velocity, and posses a mass m* that is determined by a variable two-photon detuning. The possibility of a locally adjustable mass, which is absent for any truly massive particle, allows to study a number of interesting phenomena: For example, if the

FIG. 1. (Color online) (a) 3-level Λ-type linkage pattern for the creation of slow-light polaritons. The strong control field Ω produces electromagnetically induced transparency (EIT) for the weak probe field \( \mathcal{E} \). (b) Linkage pattern with two counter-propagating control fields \( \Omega_{\pm} \) to create a stationary pattern of counter-propagating probe light \( \mathcal{E}_{\pm} \). (c) Typical experimental setup for the creation of single-component stationary light by use of two counter-propagating, mutually orthogonal control fields \( \Omega_{\pm} \). (d) Tripod-type linkage pattern for the creation of spinor slow-light polaritons (SSP).
mass of the Dirac particle is a randomly varying function of space with a vanishing mean-value, there exists a mid-gap (zero-energy) state with unusual correlations. Random-mass Dirac Hamiltonians describe a number of effects in condensed-matter systems, ranging from disordered half-filled metals [13], random anti-ferromagnetic spin-1/2 chains [4, 14, 15], random transverse-Ising spin-1/2 chains [16, 17], spin Peierls and spin-ladder systems [5, 18, 19]. Many aspects of random-mass Dirac systems are not understood, e.g. the effect of local impurities or boundaries [20] or when interactions are added. Spinor-polaritons may offer new experimental access to these issues.

We here consider light coupled to an ensemble of atoms with a linkage pattern as seen in Fig. 1d, consisting of three (meta-)stable states |g⟩, |s⟩, |h⟩ and one excited state |e⟩ with a decay rate γ. There are two pairs of counter-propagating control fields with Rabi-frequencies Ωg± e±ik_z z and Ωh± e±ik_z z on the transitions |s⟩ − |e⟩ and |h⟩ − |e⟩, respectively, as indicated in Fig. 1d. These create EIT for a pair of counter-propagating probe fields \( \hat{E}_± \), coupling the transition \(|g⟩ − |e⟩\) [2]. The use of pairs of counter-propagating control beams is essential to produce two-component slow- or stationary light, a feature missing in the ordinary tripod-type linkage pattern \([21–23]\). This scheme effectively creates EIT for a pair of counter-propagating control fields with Rabi-frequency \( \Omega \), \(|g⟩ − |e⟩\) with dipole matrix element \( ϕ \) and \( n \) is the atomic number density. Furthermore \( \hat{σ} = \text{diag}(δ_+, δ_-) \), \( Ω = \left( \begin{array}{cc} Ω_g+ & Ω_h+ \\ Ω_g- & Ω_h- \end{array} \right) \), \( \Gamma = \text{diag}(γ_{ge+} − iΔ_+, γ_{ge−} − iΔ_-) \).

Finally \( \hat{F}_P \) are Langevin noise forces necessary for preserving the commutation relations of the decaying variables \( \hat{P} \). For an exponential decay these operators are \( χ \)-correlated in time, i.e. \( \langle \hat{F}_A(t)\hat{F}_B(t') \rangle = D_{AB}δ(t − t') \), where the diffusion coefficients \( D_{AB} \) are proportional to the population of the excited states and can be calculated by means of the dissipation-fluctuation theorem \([26]\). With the help of a generalized Morris-Shore transformation \([27]\), one can show that in linear response this system has two adiabatic eigensolution that are decoupled from the excited states. If we choose the control fields such that \( Ω = \frac{i}{2 φ} (I + iσ_x) \), where \( σ_x \) is a Pauli matrix, the eigensolution of the tripod systems, the dark-state polaritons (DSP), are

\[
\hat{ψ}_+ = \cos θ \hat{E}_+ − \frac{1}{\sqrt{2}} \sin θ (\hat{σ}_{gs} - i\hat{σ}_{gh}) \quad (2)
\]

\[
\hat{ψ}_- = \cos θ \hat{E}_− + \frac{1}{\sqrt{2}} \sin θ (i\hat{σ}_{gs} - \hat{σ}_{gh}) \quad (3)
\]

where \( \tan^2 θ = g^2 n / Ω_0^2 \) is the mixing angle between light and matter excitation. We emphasize that in contrast to ordinary stationary light where only one independent dark polariton exists \([27]\) we here have two independent dark eigensolutions. We now introduce a small two-photon detuning of opposite sign \( δ = δ_e = -δ_h \) for the transitions \(|g⟩ − |s⟩\) and \(|g⟩ − |h⟩\), respectively, with \(|δ| \ll Ω_0^2 / γ \). Assuming one-photon resonance, i.e. \( Δ± = 0 \), setting \( γ_{ge±} = γ \), and transforming eq. (1) to the polariton basis and adiabatically eliminating all...
variables except for the DSPs, we arrive at
\[
i\hbar \frac{\partial}{\partial t} \hat{\Psi} = \left( i\hbar v_\mathbf{k} \sigma_z \frac{\partial}{\partial z} + \hbar \delta \sin^2 \theta \sigma_y \right) \hat{\Psi} - iL_{abs}v_\mathbf{k} \sin^4 \theta \left( \sigma_z \frac{\partial}{\partial z} - \frac{\delta}{c} \sigma_y \right)^2 \hat{\Psi} + \hat{F}_\mathbf{\Psi}. \tag{4}
\]

Eq. (4) represents a Dirac equation for a spinor \( \hat{\Psi} = (\hat{\Psi}_+, \hat{\Psi}_-) \) with effective ”speed of light” and mass
\[
c^* = v_\mathbf{k} = c \cos^2 \theta, \quad m^* = \frac{\hbar \delta \sin^2 \theta}{v_\mathbf{k}^2}. \tag{5}
\]

The imaginary quadratic term in (4) results from non-adiabatic couplings to decaying states, \( \hat{F}_\mathbf{\Psi} \) is the corresponding Langevin-noise operator. \( L_{abs} = c_\gamma / q^2 n \) is the resonant absorption length in absence of EIT, \( \sigma_z \) and \( \sigma_y \) denote Pauli matrices. From eq. (4) we expect a Dirac cone structure of the dispersion relation as seen in Fig.2. The interaction of the control fields with the atoms results in two Autler-Townes states represented in Fig.2. The interaction of the control fields with the free probe fields is given by the almost vertical black dashed lines. Switching on the interaction, the red dotted dispersion branches are formed. These correspond to the two components of the slow-light spinor and are in a very good approximation described by the expected Dirac dispersion with \( c^* = v_\mathbf{k} \) around \( k = 0 \) (orange dashed line).

Finally inducing a small two-photon detuning \( \delta \) results in a finite mass \( m^* \), as can be seen by the finite splitting of the blue (solid) line.

To confirm the effective model, we numerically integrated the full set of MBE for the scheme of Fig. 1d in time for the case of \( m^* = 0 \). The results showed very good agreement with the analytic prediction.

We now exploit the property of a locally adjustable mass of the SSP. If at a certain point along the \( z \)-axis the mass changes its sign, i.e. \( m_0 \to -m_0 \), one can easily show, that there exists a localized mid-gap (i.e. zero energy) solution around the mass jump, as by squaring the Dirac Hamiltonian leads to a pair of supersymmetric Hamiltonians corresponding to two independent particles, described by a Schrödinger equations with a Dirac-\( \delta \) potential. The zero-energy bound state is exponentially localized with a localization length proportional to the effective Compton length \( \lambda_C = \hbar / (m^* c^*) \). This is indicated in Fig. 3.

Thus one can ask how the state will look like when the number of mass jumps and their size is increased? This leads to the 1D random-mass Dirac model: Given a spatially random mass \( m(z) \), with \( \hbar = c = 1 \)
\[
\langle m(z)m(y) \rangle = 2\Gamma \delta(z-y), \quad \langle m(z) \rangle = 0, \tag{6}
\]

where \( \Gamma \) parameterizes the strength of the disorder, it was shown [4, 5] that the density of states at zero energy is diverging, corresponding to a localized state. The corresponding wave function \( \Psi(z) \) exposes however unusual density correlations. Contrary to expectations there is not an exponential localization as in the case of Fig.3 but one finds for \( \Gamma z \gg 1 \):
\[
\frac{|I(z)I(0)|}{|\langle \Psi(z) \rangle^2|} \sim \left( \frac{1}{\Gamma z} \right)^{3/2}, \tag{7}
\]

where \( I(z) = |\langle \Psi(z) \rangle|^2 \). A spatially varying mass (detuning \( \delta \)) can be achieved by using fluctuating magnetic fields or by applying speckle patterns as done for the demonstration of Anderson localization [28].

In experiments one has a finite correlation length \( \xi \) of the disorder which we use as a discretization length for the simulations. We assume that the two-photon detuning has a Gaussian distribution with \( \overline{\delta} = 0 \) and \( \overline{\delta^2} = \sigma^2 \) for all points in space.

In Fig. 4 numerical results of the density correlation
(7) are shown obtained from the full MBE. For large times the correlation (red solid line) approaches the predicted power-law behavior, shown by the black dashed line.

The finite two-photon detuning also leads to some small losses, seen in the inlet of Fig. 4. Two regimes are apparent: The first rapid loss is due to imperfect matching of the initial wave function to the zero-energy eigenstate. The smaller losses for large times can be attributed to non-adiabatic couplings of the SSP to decaying states, resulting in an effective loss rate \( \gamma_{\text{eff}} = \pi^2 L_{\text{abs}} v_g / L_0^2 \), \( L_0 \) being some characteristic length scale of the localized state. These losses are negligible as long as \( \gamma_{\text{eff}} T \ll 1 \), where \( T = L / v_g \) is the typical time scale of the experiment. Furthermore (7) requires \( \Gamma L \gg 1 \), in order to observe the power-law decay. This translates to \( L \gg v_g^2 n_{\text{kinks}} / \sigma^2 \sin^4 \theta \equiv L_{\text{corr}} \), where \( n_{\text{kinks}} \) is the number density of mass jumps. Both equations finally lead to \( L / L_{\text{abs}} \equiv OD \gg \max \left\{ \frac{\alpha_1}{\gamma_0} \sqrt{N_{\text{kinks}}} \left( \frac{\pi L}{L_0} \right)^2 \right\} \). Here \( N_{\text{kinks}} = n_{\text{kinks}} L \) is the number of kinks in the length \( L \) and \( OD \) denotes the optical depth of the medium. For white noise the mean free path \( \lambda_{\text{mean}} = n_{\text{kinks}} \) can be approximated by the disorder correlation length \( \xi \), i.e. \( \lambda_{\text{mean}} = \xi \). Taking \( \xi \approx 0.3 \mu \text{m} \), \( L \approx 4 \text{ mm} \) [28], and estimating \( N_{\text{kinks}} = L / \xi \approx 10^4 \) yields a required optical depth of \( OD \gtrsim 100 \). This high optical depth is however achievable in systems such as atoms trapped in a hollow core photonic bandgap fiber [29] or cold atoms trapped in the evanescent fields of an ultra-thin optical fiber [30].

An estimate of the minimal build-up time of the correlations, defined as \( T_{\text{corr}} = L_{\text{corr}} / v_g \) yields \( T_{\text{corr}} \approx 2.5 - 25 \mu \text{s} \). Here we used \( \sigma \approx 0.1 \gamma = (2\pi)(0.6 \text{MHz}) \) (for \(^{87}\text{Rb}\) ), \( v_g \approx 10 - 100 \text{ m/s} \) [3] and the correlation length \( \xi \approx 0.3 \mu \text{m} \) from above. This time is far shorter than the achievable lifetime of the dark-state polaritons, typically on the order of \( 100 \mu \text{s} \) [6] to several ms [11, 12], thus enabling experimental observation.

A possible experimental protocol to observe the proposed effect is to store an initial wave packet in the atomic coherences with existing storing techniques for slow-light polaritons [6] or by coherent RF-transitions [31]. Subsequently one applies the disorder, e.g. by a laser-speckle induced ac-Stark shifts and reads out the polaritons by applying all four control fields. The polariton states then evolve according to the above presented model. After a certain time the disorder is removed and the final state is read out by means of usual slow-light. Looking at the time profile of the intensity of the probe fields arriving at the detector one can reconstruct the spatial intensity profile of the localized state.

In summary we have shown that the coupling of two counter-propagating light fields to an optical thick ensemble of atoms driven by multiple drive fields in a tripod-like linkage pattern leads to the formation of spinor-like eigensolutions which are immune to spontaneo us emission losses. These spinor dark-state polaritons obey a 1D Dirac equation with effective speed \( c^* \) given by the group velocity of slow-light in EIT media and with an effective mass \( m^* \) determined by a small two-photon detuning. This allows to experimentally study a number of interesting phenomena of relativistic quantum dynamics. For example the possibility to tune the effective mass can be used to observe the unusual localization transition predicted for the random-mass Dirac model, which appears in the context of several interesting condensed matter systems with disorder. Furthermore adding interactions, e.g. by means of resonantly enhanced Kerr nonlinearities [32], important relativistic many-body models such as the bosonic counterpart of the Thirring model [33] should be experimentally accessible.
