Fractional Langevin equation from damped bath dynamics

Alex V. Plyukhin
Saint Anselm College, Manchester, New Hampshire
(Dated: May 20, 2019)

We consider the stochastic dynamics of a system linearly coupled to a hierarchical thermal bath with two well-separated inherent timescales: one slow, and one fast. The slow part of the bath is modeled as a set of harmonic oscillators and taken into account explicitly, while the effects of the fast part of the bath are simulated by dissipative and stochastic Langevin forces, uncorrelated in space and time, acting on oscillators of the slow part of the bath. We demonstrate for this model the robust emergence of a fractional Langevin equation with a power-law decaying memory kernel. The conditions of such an emergence and the specific value of the fractional exponent depend only on the asymptotic low-frequency spectral properties of the slow part of the bath.

The fractional Langevin equation (FLE) is a special, and important, type of the generalized (non-Markovian) Langevin equation \(^1\) for a dynamical variable \(A\) coupled to a thermal bath,

\[
\dot{A}(t) = -\int_0^t K(t - \tau) A(\tau) \, d\tau + F(t),
\]

with the algebraically decaying memory kernel \(K(t)\). We shall focus on kernels with the decay exponent \(\alpha\) being less than one,

\[
K(t) = K_0 \, t^{-\alpha}, \quad 0 < \alpha < 1,
\]

in which case the FLE describes subdiffusion \(^2\) \(^3\). The term \(F(t)\) in \(^1\) is a zero-centered stationary noise, which is related to the kernel by the fluctuation-dissipation theorem \((F(t)F(t')) = k_B T K(t-t')\) where \(T\) is temperature. If an external force is also applied (not considered here), it is assumed not to modify the kernel. Equation \(^1\) with kernel \(^2\) is called "fractional" because if \(A = \dot{A}\) then the nonlocal term in \(^1\) is proportional to the Caputo fractional derivative \(D_t^{-\alpha} A(t) = \frac{1}{\Gamma(1-\alpha)} \int_0^t (t - \tau)^{-\alpha} \dot{A}(\tau) \, d\tau\).

Although writing the FLE in terms of the fractional derivative may be insightful \(^4\), the equation can be, and often is, exploited with no tools specific to fractional calculus.

Among other types of generalized Langevin equations, the FLE is distinguished by the diverging integral \(\gamma = \int_0^\infty K(t) \, dt\), which in other cases gives the friction constant \(\gamma\) in the Markovian approximation. Therefore, there is no Markovian approximation for the FLE. A physical consequence of this mathematical property, as was noticed above, is anomalous diffusion: If \(A\) stands for the velocity \(\dot{x}\) of a Brownian object, then the FLE predicts subdiffusion, i.e. the mean-square displacement \(<x^2(t)>\) increasing sublinearly, namely as \(t^{\alpha}\) \(^2\) \(^3\) \(^4\). Another peculiarity is that stochastic processes governed by the FLE exhibit nontrivial ergodic properties \(^4\).

As a matter of fact, the aforementioned unique features of the FLE still hold if the power-law dependence \(\gamma \propto t^{\alpha}\) takes place not for the entire time domain, but only asymptotically at long times,

\[
K(t) \sim t^{-\alpha}, \quad 0 < \alpha < 1, \quad \text{as} \quad t \to \infty.
\]

One may call equations with kernels \(^3\) asymptotically fractional, but we prefer to keep to the established term FLE for such equations as well, even though in that case the nonlocal term in \(^1\) may lose the meaning of a fractional derivative.

The FLE was first introduced on a phenomenological basis to describe anomalous diffusion in geometrically disordered and fractally organized systems like percolation clusters \(^6\). The existence of a dynamical theory giving rise to the FLE is far from obvious and was explicitly doubted \(^5\). Later studies, however, suggested that the origin of the FLE in many phenomena, particularly protein conformational transitions, may be purely dynamical \(^7\) \(^8\). Is there a specific feature of inherent dynamics in complex systems characteristic of subdiffusion and emergence of the FLE?

A standard model to formally derive a generalized Langevin equation with a memory kernel of any assigned form is that of a Brownian particle linearly coupled to the bath comprised of independent harmonic oscillators \(^1\) \(^10\). In such a setting, the memory kernel can be expressed as a Fourier transform of a certain function \(C(\omega)\), describing spectral properties of the bath and bath’s coupling to a system (see below). Assuming that

\[
C(\omega) = C_0 \omega^\beta, \quad -1 < \beta < 0,
\]

one recovers the fractional kernel \(^2\) with the exponent \(\alpha = 1 + \beta\) \(^11\). Other approaches to derive the FLE were considered in \(^10\) \(^12\) \(^13\).

In this paper we show that with additional dissipative forces acting on the bath oscillators the aforementioned standard model leads to the FLE under a much less restrictive condition. It still has the form \(^4\), but for a larger range of \(\beta\), namely \(-1 < \beta < 1\). For the the fractional exponent our model predicts \(\alpha = (1 + \beta)/2\) instead of \(\alpha = 1 + \beta\) for the standard model. More importantly, the power-law dependence of the spectral function \(C(\omega)\) is required not for the entire frequency range (as in the standard model), but only asymptotically in the limit.
\( \omega \to 0 \), see Eq. (30) below. We argue that a rather relaxed character of this condition may explain the omnipresence of fractional stochastic dynamics in a wide range of complex systems.

We start with an observation that in many systems exhibiting fractional stochastic dynamics the thermal bath involves two groups of dynamical variables evolving on well-separated timescales. The separation of timescales for a system of interest on the one hand, and for the bath variables on the other hand is, of course, a common feature in many statistical mechanical models. In contrast, a specific assumption of the presented model is that the separation of timescales takes place for the bath alone. For brevity, we shall refer to the parts of the bath comprising slow and fast variables as the slow and fast baths, respectively, assuming that both baths have the same temperature. For a macromolecule in a solvent \([8, 9]\), the presence of fractional stochastic dynamics in a wide variety in many statistical mechanical models. In contrast, a specific assumption of the presented model is that the independent oscillators represents collective normal modes of the slow bath rather than the bath’s individual constituents.

The equations of motion corresponding to the above Hamiltonian read

\[
\dot{P} = \sum_{i=1}^{N} \gamma_i \left( q_i - \frac{\gamma_i}{\omega_i^2} Q \right), \quad (7)
\]

\[
\dot{p}_i = -\omega_i^2 q_i + \gamma_i Q. \quad (8)
\]

These equations are identical to those of the standard oscillator bath model \([1, 10]\) and yet do not take into account the presence of the fast bath. The effects of the latter we describe by adding time-local Langevin forces

\[
f_i = -2\lambda p_i + \xi_i, \quad (9)
\]

acting on \(i\)-th oscillator of the slow bath. Here the white noise forces \(\xi_i(t)\) are zero-centered and related to the damping coefficient \(\lambda\) (assumed to be the same for all oscillators) by the fluctuation-dissipation relations

\[
\langle \xi_i(t) \xi_{i'}(t') \rangle = 4\lambda k_B T \delta(t - t') \delta_{ii'}. \quad (10)
\]

Here the Kronecker symbol \(\delta_{ii'}\) implies that stochastic forces \(\xi_i\) acting on different oscillators are uncorrelated.

With the Langevin forces added, the equations of motions for the slow bath oscillators \([8]\) take the form

\[
\dot{q}_i = -\omega_i^2 q_i + \gamma_i Q - 2\lambda p_i + \xi_i. \quad (11)
\]

Replacing momenta by velocities, \(p_i = \dot{q}_i\), one can rewrite this as equations for \(q_i\),

\[
\ddot{q}_i + 2\lambda \dot{q}_i + \omega_i^2 q_i = \gamma_i Q + \xi_i. \quad (12)
\]

In our model, these are equations of motion of the slow bath oscillators coupled to the particle and to the fast bath.

We shall assume that an equation of motion for the particle still has the form \([17]\), i.e. the particle is directly coupled to the slow bath only (as depicted in Fig. 1). This assumption is not essential: a coupling of the particle to the fast bath can be easily taken into account

![FIG. 1: The idealized scheme of the model: A systems of interest (the large central circle) is directly coupled to oscillators of the slow bath (medium-size inner circles), which in turn are coupled to particles of the fast bath (small outer circles). The latter are taken into account implicitly à la Langevin.](image-url)
as well, but it would have a trivial effect of an additional delta-function contribution in the final expression for the memory kernel, which does not affect the asymptotic long-time properties of the model.

Solving Eqs. 12, for instance by the method of Laplace transforms, one finds

\[ q_i(t) = q_i^0(t) + \int_0^t b_i(t - \tau) \left( \gamma_i Q(\tau) + \xi_i(\tau) \right) d\tau, \quad (13) \]

Here \( q_i^0(t) \) is a solution of the corresponding homogeneous equation \( \ddot{q}_i + 2\lambda \dot{q}_i + \omega_i^2 q_i = 0 \), which we write as

\[ q_i^0(t) = a_i(t) q_i(0) + b_i(t) \dot{q}_i(0), \quad (14) \]

where the functions \( a_i(t) \) and \( b_i(t) \) are

\[ a_i(t) = e^{-\lambda t} \left( \cosh \Omega_i t + \frac{\lambda}{\Omega_i} \sinh \Omega_i t \right), \]

\[ b_i(t) = e^{-\lambda t} \frac{\cosh \Omega_i t}{\Omega_i} \sinh \Omega_i t. \quad (16) \]

In these expressions, the frequency-like parameter

\[ \Omega_i = \sqrt{\lambda^2 - \omega_i^2} \quad (17) \]

is real for overdamped \( (\omega_i < \lambda) \) and imaginary for underdamped \( (\omega_i > \lambda) \) oscillators, yet in both cases the functions \( a_i(t) \) and \( b_i(t) \) are real-valued.

Expression 13 for \( q_i(t) \) is intended to be substituted into the equation of motion \( 17 \) in order to bring the latter into a Langevin form. To this end, the standard trick is to integrate the term with \( Q \) in 13 by parts. Taking into account that an anti-derivative of \( b_i(t) \) equals

\[ B_i(t) = \int_0^t b_i(\tau) d\tau = \frac{1}{\Omega_i^2} \left( 1 - a_i(t) \right), \quad (18) \]

one brings expression 13 into the form

\[ q_i(t) = q_i^0(t) - \gamma_i \frac{\Omega_i}{\omega_i^2} \int_0^t a_i(t - \tau) \dot{Q}(\tau) d\tau + \frac{\gamma_i}{\omega_i^2} Q(t) \]

\[ - \frac{\gamma_i}{\omega_i^2} a_i(t) Q(0) + \int_0^t b_i(t - \tau) \xi_i(\tau) d\tau. \quad (19) \]

Substitution of this expression into the particle’s equation of motion \( 7 \) yields the generalized Langevin equation

\[ \ddot{P}(t) = - \int_0^t K(t - \tau) P(\tau) d\tau + F(t), \quad (20) \]

with the memory kernel

\[ K(t) = \frac{1}{M} \sum_{i=1}^N \left( \frac{\gamma_i}{\omega_i^2} \right)^2 a_i(t) \quad (21) \]

and the noise force

\[ F(t) = \sum_{i=1}^N \gamma_i \left\{ q_i^0(t) - \frac{\Omega_i}{\omega_i^2} a_i(t) Q(0) + \int_0^t b_i(t - \tau) \xi_i(\tau) d\tau \right\}. \]

If there is no fast bath, then \( (\lambda, \xi_i) \to 0 \), and the above expressions coincide with that for the standard oscillator bath model 1, 10. Suppose the initial state of the slow bath is described by a canonical ensemble with the Hamiltonian \( H_b \) given by 9, then one can show that the noise \( F(t) \) is zero-centered, \( \langle F(t) \rangle = 0 \), and the fluctuation-dissipation relation between \( F(t) \) and \( K(t) \) can be readily established.

Next, we make a usual assumption that in the limit \( N \to \infty \) the spectrum of the slow bath becomes continuous, \( \{\omega_i\} \to \omega \), and the sums over \( i \) can be replaced by integrals, \( \sum_i \to \int_0^\infty d\omega g(\omega) \langle \cdots \rangle \), where \( g(\omega) \) is the density of the slow bath states 1, 10, 14. Replacing the coupling constants and functions \( a_i(t) \) of individual oscillators by smooth functions of frequency,

\[ \gamma_i \to \gamma(\omega), \quad a_i(t) \to a(t, \omega), \quad (22) \]

the memory kernel 21 can be written in the form

\[ K(t) = \frac{1}{M} \int_0^\infty d\omega C(\omega) a(t, \omega) \quad (24) \]

defining the function

\[ C(\omega) = \frac{1}{M} g(\omega) \frac{\gamma(\omega)^2}{\omega^2} \quad (25) \]

which accumulates the spectral properties of the slow bath.

As follows from 15 and 24, the Laplace transform of the kernel \( \tilde{K}(s) = \int_0^\infty e^{-st} K(t) dt \) reads

\[ \tilde{K}(s) = \int_0^\infty d\omega C(\omega) \frac{s + 2\lambda}{s^2 + 2\lambda s + \omega^2}. \quad (26) \]

According to a Tauberian theorem 15, the long-time behavior of the kernel \( K(t) \) is determined by the behavior of its Laplace transform \( \tilde{K}(s) \) at small \( s \) as follows:

\[ \tilde{K}(s) \sim s^{-\gamma} \text{ as } s \to 0 \quad \Rightarrow \quad K(t) \sim t^{\gamma - 1} \text{ as } t \to \infty. \quad (27) \]

In order to find an asymptotic form of \( \tilde{K}(s) \) for small \( s \), one can neglect \( s \) in the numerator and \( s^2 \) in the denominator of the integrand of 26. Then it can be written as

\[ \tilde{K}(s) = \pi \sqrt{\frac{2\lambda}{s}} \int_0^\infty d\omega C(\omega) \frac{L(\omega, \sqrt{2\lambda s})}{\sqrt{\omega^2 + 2\lambda s}}, \quad (28) \]

where \( L(\omega, \Gamma) \) is the zero-centered Lorentzian (or Cauchy) distribution

\[ L(\omega, \Gamma) = \frac{1}{\pi} \frac{\Gamma}{\omega^2 + \Gamma^2}. \quad (29) \]
and has the asymptotic form

\[ s \rightarrow 0 \quad \text{and for } s \rightarrow 0 \] the kernel \( \tilde{K}(s) \) is determined by the first part, diverging for small \( s \),

\[ \tilde{K}(s) \approx \pi \sqrt{\frac{2\lambda}{s}} \int_0^e C(\omega) L(\omega, \sqrt{2\lambda s}) \, d\omega \]

\[ \propto \, zF1\left(1, \frac{1 + \beta}{2}, \frac{3 + \beta}{2}, -\frac{e^2}{2\lambda s}\right) \frac{e^{1 + \beta}}{(1 + \beta) s}. \]

Taking into account asymptotic properties of the Gauss hypergeometric function \( zF1(a, b; c; z) \) at large \( z \), one recovers from (32) the power-law asymptotic behavior.

Finally, using the Tauberian theorem, one finds that in the time domain the kernel has a fractional asymptotic form,

\[ K(t) \sim t^{-\alpha}, \quad \alpha = 1 - \gamma = \frac{1}{2}(1 + \beta). \]

Since we assume \(-1 < \beta < 1\), then \( 0 < \alpha < 1 \).

The above asymptotic arguments can be illustrated with specific spectral functions defined for the entire frequency range. As an example consider

\[ C(\omega) = \frac{C_0}{1 + \tau^2 \omega^2}. \]

In the standard oscillator bath model, the memory kernel is a Fourier transform of \( C(\omega) \), \( K(t) = \int_0^\infty d\omega C(\omega) \cos(\omega t) \), and for the spectral function \( C(\omega) \) takes the exponential form \( K(t) = K_0 e^{-|t|/\tau} \). Instead, in the present model the corresponding kernel is fractional and its dependence on \( \tau \) disappears: since \( C(\omega) \sim \omega^\beta \) as \( \omega \rightarrow 0 \), then \( \beta = 0 \), and Eq. (33) predicts \( K(t) \sim t^{-1/2} \). The exact evaluation of the kernel by substituting \( C(\omega) \) of the form \( 2(1 + \beta) \) into (28) confirms this result.

Another example is the spectral function \( C(\omega) = C_0 \omega^\beta e^{-\tau^2 \omega^2} \), with \(-1 < \beta < 1 \). Again, the direct evaluation of the kernel using (28) confirms the asymptotic kernel’s behavior.

In the above examples, the emergence of fractional kernel \( C(\omega) \) depends neither on \( \tau \), nor on \( \lambda \) (the parameters characterizing the slow and fast baths, respectively), but only on low-frequency spectral properties of the slow bath. This illustrates the robustness of fractional dynamics in the presented model.

In conclusion, the presented model shows that the fractional Langevin dynamics may emerge under much broader conditions than some earlier models suggested. The conditions concern the bath’s asymptotic low-frequency properties only. Although modeling of the slow bath as a set of independent oscillators may appear on first glance unrealistic, it is in fact physically well-motivated and relevant for systems like lattices and networks, whose Hamiltonian can be diagonalized, exactly or approximately, into a sum of contributions from independent collective normal modes. As a simple illustration one may point to the familiar problem of a

---

**Figure 2:** The integrand function \( D(\omega) = C(\omega) L(\omega, \sqrt{2\lambda s}) \) of the kernel (28) for \( C(\omega) = \omega^\beta \) with \( \beta = 0.7 \) and several values of the Laplace variable \( s \) (arb. units).
tagged particle, or an isotope, in an otherwise uniform one-dimensional harmonic lattice immersed in a fluid. The problem can be mapped into the model discussed in this paper with the chain’s normal modes serving as independent oscillators of the slow bath, and the fluid as a fast Langevin bath. For the linear harmonic chain the explicit expressions for the normal mode $g(\omega)$ and coupling $\gamma(\omega)$ distributions are well-known \[14\]. Then for the spectral function \[25\] one finds the asymptotic dependence $C(\omega) \sim \omega^0$ as $\omega \to 0$. Accordingly $\beta = 0$, and for the tagged particle’s momentum our model predicts the FLE with the fractional exponent $\alpha = (1 + \beta)/2 = 1/2$. For an over-damped chain this is a well-known result \[12\], but here we get it for an arbitrary level of damping.
