Chagas disease is produced by the parasite Trypanosoma cruzi (T. cruzi), which is the leading cause of death and morbidity in Latin America. We have shown that in patients with Chagas cardiomyopathy, there is a chronic elevation of diastolic Ca²⁺ concentration ([Ca²⁺]d), associated with deterioration to further address this issue, we explored the role Na⁺/Ca²⁺ exchanger (NCX). Experiments were carried out in noninfected C57BL/6 mice and infected with blood-derived trypomastigotes of the T. cruzi Y strain. Anesthetized mice were sacrificed and the cardiomyocytes were enzymatically dissociated. Diastolic [Ca²⁺]d ([Ca²⁺]d) was measured using Ca²⁺ selective microelectrodes in cardiomyocytes from control mice (CONT) and cardiomyocytes from T. cruzi infected mice in the early acute phase (EAP) at 20 dpi, in the acute phase (AP) at 40 dpi, and in the chronic phase (CP) at 120 dpi. [Ca²⁺]d was 1.5-times higher in EAP, 2.6-times in AP, and 3.4-times in CP compared to CONT. Exploring the reverse mode activity of NCX, we replaced extracellular Na⁺ in equivalent amounts with N-methyl-D-glucamine. Reduction of [Na⁺]e to 65 mM caused an increase in [Ca²⁺]d of 1.7 times in cardiomyocytes from CONT mice, 2 times in EAP infected mice, 2.4 times in AP infected mice and 2.8 in CP infected mice. The Na⁺ free solution caused a further elevation of [Ca²⁺]d of 2.5 times in cardiomyocytes from CONT, 2.8 times in EAP infected mice, 3.1 times in AP infected mice, and 3.3 times in CP infected mice. Extracellular Ca²⁺ withdrawal reduced [Ca²⁺]d in both CONT and cardiomyocytes from Chagas-infected mice and prevented the increase in [Ca²⁺]d induced by Na⁺ depletion. Preincubation with 10µM KB-R7943 or in 1µM YM-244769 reduced [Ca²⁺]d in cardiomyocytes from infected mice, but not control mice. Furthermore, both NCX blockers prevented the increase in [Ca²⁺]d associated with exposure to a solution without Na⁺. These results suggest that Ca²⁺ entry through the reverse NCX mode plays a significant role in the observed [Ca²⁺]d dyshomeostasis in Chagas infected cardiomyocytes. Additionally, NCX inhibitors may be a viable therapeutic approach for treating patients with Chagas cardiomyopathy.

Keywords: chagas disease, Na/Ca exchanger, cardiomyopathy, Trypanosoma cruzi (T cruzi), calcium
INTRODUCTION

Chagas disease, caused by the protozoan Trypanosoma cruzi (T. cruzi), affects approximately eight million people in the poorest areas of Central and South America. The prevalent form of transmission of T. cruzi to humans is contact with contaminated feces/urine of the invertebrate vector during a blood meal. However, human infection through blood transfusion, organ transplantation and oral. (Bern et al., 2008) and oral transmission due to ingestion of contaminated fruit juices (Alarcon De Noya et al., 2010) have been reported. Chagas disease is characterized by a varied clinical scenario that evolves from an acute phase, often asymptomatic or oligosymptomatic, to a chronic phase that can manifest as indeterminate, cardiac, or digestive forms (Echavarria et al., 2021). Most infected people show that NCX activity is enhanced in cardiomyocytes from T. cruzi-infected mice compared to control cardiomyocytes and that the reverse mode of NCX contributes to intracellular Ca\(^{2+}\) dyshomeostasis observed in cardiomyocytes from infected mice.

MATERIAL AND METHODS

Animals

Homozygous male C57BL/10 with a bodyweight of 25 ± 0.45 g, and 12 weeks of age were housed at constant temperature (24°C) and a 12 h light/12 h dark cycle, with free access to water and fed a commercial pelleted diet.

Trypanosoma cruzi Infection

Mice were randomly divided into two groups: Group A (Control) that were not inoculated with T. cruzi and Group B (infected mice) were infected intraperitoneally with 5x10^{-2} blood-form trypomastigotes of the Y strain of T. cruzi (O’Daly et al., 1984). The Y strain of T. cruzi was originally obtained from patients in Brazil and was kindly provided by Dr. Jose O’Daly, who has maintained the strain over the years through serial passages in homoygous C57B1/6 mice. Parasitemia was monitored by counting the number of parasites/5 µl of blood obtained from the tail vein of infected mice. A positive parasitemia was found in all inoculated animals on days 12-15 post-infection (dpi). Non-infected and infected anesthetized (ketamine/xylazine) mice were sacrificed by cervical dislocation at 20 (early acute phase), 40 (acute phase), and 120-dpi (chronic phase), and the cardiomyocytes were enzymatically dissociated.

Isolation of Cardiomyocytes and Inclusion Criteria

Control and infected mice were anesthetized (ketamine 100 mg/kg/xylazine 5 mg/Kg) and hearts were rapidly removed, attached to a cannula, and mounted on a Langendorff reverse coronary perfusion system for the enzymatic dissociation of ventricular cardiomyocytes (Liao and Jain, 2007). Only Ca\(^{2+}\) tolerant cardiomyocytes with rod-shaped, well-defined striation spacing and a resting sarcomere length of ≥1.75 µm (Wussling et al., 1987) were used and studied within 4-6 h after isolation. The isolation procedure was carried out at 37°C.

Ca\(^{2+}\) and Na\(^{+}\) Selective Microelectrodes

Double-barreled Ca\(^{2+}\) and Na\(^{+}\) selective microelectrodes were prepared as previously described (Eltit et al., 2013). Each ion-selective microelectrode was individually calibrated before and after the determination of [Ca\(^{2+}\)]\(_{d}\) and the [Na\(^{+}\)]\(_{d}\) as previously described (Mijares et al., 2014). Ca\(^{2+}\) selective microelectrodes with a Nernstian response between pCa3 and pCa7 (30.5 mV/pCa units at 37°C) and Na\(^{+}\) selective microelectrodes with Nernstian responses between 100 and 10 mM [Na\(^{+}\)]\(_{e}\) and an adequate response (40–45 mV) between 10 and 1 mM [Na\(^{+}\)]\(_{d}\) were used experimentally (Lopez et al., 1983; Lopez et al., 2000; Eltit et al., 2013). The Ca\(^{2+}\) and Na\(^{+}\) microelectrode response was not affected by any of the drugs used in the present study.

In the present study, we evaluated the activity of NCX in cardiomyocytes from control and Chagas infected mice. We showed that NCX activity is enhanced in cardiomyocytes from T. cruzi-infected mice compared to control cardiomyocytes and that the reverse mode of NCX contributes to intracellular Ca\(^{2+}\) dyshomeostasis observed in cardiomyocytes from infected mice.
Recording of Diastolic Calcium and Sodium Concentrations

Isolated cardiomyocytes from control mice and T. cruzi infected mice were impaled with double-barrel Ca$^{2+}$ or Na$^+$ microelectrodes to measure [Ca$^{2+}$]$_d$ and [Na$^+$]$_d$ respectively, and potentials were recorded using a high impedance electrometer (WPI 773 electrometer, FL, USA) as previously described (Lopez et al., 2000; Lopez et al., 2017). The potential of the 3M KCl microelectrode barrel (Vm) was electronically subtracted from the potential recorded by the Ca$^{2+}$ selective barrel (V$_{Ca}$) to produce a differential Ca$^{2+}$ specific potential (V$_{CaE}$) that represents the cardiomyocyte [Ca$^{2+}$]$_d$. A similar approach was used to produce the specific Na$^+$ potential (V$_{NaE}$), which represents the cardiomyocyte [Na$^+$]$_d$. The potentials were acquired at a frequency of 1,000 Hz with the AxoGraph software (version 4.6; Axon Instruments, CA, USA) and stored in a computer for further analysis.

Individual cardiomyocyte measurements of [Ca$^{2+}$]$_d$ and [Na$^+$]$_d$ from control and infected mice were accepted when there was i) an abrupt drop to a steady level of Vm equal to or more negative than -80 mV in healthy cells and -70 mV in unhealthy cardiomyocytes; ii) a stable recording of Vm and V$_{Ca}$ potentials or Vm and V$_{Na}$ potentials for more than 60 seconds and an abrupt return to baseline at the exit of the microelectrode from the cell. Vm was used as a biological indicator of the integrity of cardiomyocyte sarcolemna in real-time; therefore, any cardiomyocytes with a recorded Vm <-70 mV were discarded. These criteria were not met in 18% of total impalements performed in cardiomyocytes from control mice and 41% in infected mouse cardiomyocytes.

Reverse Mode NCX Protocol

The effect of NCX (reverse mode) on [Ca$^{2+}$]$_d$ in cardiomyocytes from control and infected mice was determined by preincubating cardiomyocytes in a solution in which [Na$^+$]$_e$ was partially or completely removed (see solutions below) and replaced by N-methyl-D-glucamine hydrochloride. Measurements of [Ca$^{2+}$]$_d$ were carried out before and after incubation in low Na$^+$ solutions.

Equilibrium Potentials

The equilibrium potentials for Ca$^{2+}$ ($E_{Ca}$) and Na$^+$ ($E_{Na}$) were calculated using the Nernst equation ($E_{ion} = RT/2F \times \ln [ion]_i/ [ion]_o$) and [Ca$^{2+}$]$_d$ and [Na$^+$]$_d$ obtained in cardiomyocytes from CONT and infected mice in EAP, AP, and CP. The equilibrium potential of the Na$^+$/Ca$^{2+}$ exchanger ($E_{NCX}$) was estimated using the following equation: $E_{NCX} = 3E_{Na} - 2E_{Ca}$ (with a stoichiometry of 3:1), where $E_{Na}$ and $E_{Ca}$ are the equilibrium potentials of Na$^+$ and Ca$^{2+}$ obtained from the Nernst equation.

Solutions

All solutions were made with ultrapure water supplied by a Milli-Q system (Millipore, Bedford, MA). The Tyrode solution had the following composition (in mM): 130 NaCl, 5 KCl, 2.5 CaCl$_2$, 1 MgCl$_2$, 20 NaHCO$_3$, 0.33 NaH$_2$PO$_4$, and 10 glucose gassed with 95% O$_2$ and 5% CO$_2$, pH 7.4. A low- or Na$^+$-free solution was prepared by the partial or total withdrawal of [Na$^+$]$_o$ and replacement by an equivalent amount of impermeable cation N-methyl-D-glucamine (NMG) hydrochloride to maintain osmolarity. A Ca$^{2+}$-free solution was prepared, omitting CaCl$_2$ and adding 1 mM of EGTA and 2 mM of MgCl$_2$. Solutions 2-2 (4.4-nitrobenzoxo-phenyl-ethyl-isothiourea methanesulfonate (KB-R7943) and N- (3-aminobenzyl) -6- 4- [(3-fluorobenzyl-ox) phenoxy nicotinamide (YM-244769) were made by adding the desired concentration of the reagent to the Tyrode solution. All experiments were carried out at 37°C.

Statistical Analysis

Experimental results are expressed as means ± SD; $n_{mice}$ represents the number of mice used and $n_{cells}$ the number of successful measurements in cardiomyocytes isolated from CONT and infected mice used for statistical analysis. Data were analyzed using one-way analysis of variance ANOVA for repeated measures, followed by Tukey’s multiple comparison tests to determine significance. A $p$ <0.05 was considered significant. GraphPad Prism 9 (GraphPad Software, CA, USA) was used for statistical analysis.

RESULTS

[Ca$^{2+}$]$_d$ and [Na$^+$]$_d$ in Ventricular Cardiomyocytes of Chagasic Rodents

We previously reported a significant elevation in [Ca$^{2+}$]$_d$ in cardiomyocytes obtained from patients with chronic Chagas cardiomyopathy, which was related to the extent of their cardiac dysfunction (Lopez et al., 2011; Mijares et al., 2020). Figure 1 shows representative records of simultaneous measurement of Vm and [Ca$^{2+}$]$_d$ in a single cardiomyocyte isolated from (A) CONT mice, (B) EAP-infected mice (20 dpi), (C) AP-infected mice (40 dpi), and (D) CP-infected mice (120 dpi). The cardiomyocytes of Chagas-infected mice showed partial depolarization and increased [Ca$^{2+}$]$_d$ which aggravated as a function of days after infection. The mean Vm and [Ca$^{2+}$]$_d$ in quiescent cardiomyocytes from CONT mice were 81 ± 1 mV and 122 ± 3 nM. Respectively. In cardiomyocytes from EAP-infected mice, Vm was 78 ± 1.7 mV and [Ca$^{2+}$]$_d$ 194 ± 23 nM ($p$<0.001 compared to CONT cardiomyocytes); in cardiomyocytes from AP-infected mice, Vm was 76 ± 1.6 mV and [Ca$^{2+}$]$_d$ 320 ± 38 nM ($p$<0.001 compared to CONT cardiomyocytes) and in cardiomyocytes from CP-infected mice, Vm was 72 ± 1.8 mV and [Ca$^{2+}$]$_d$ 470 ± 43 nM ($p$<0.001 compared to CONT cardiomyocytes) (Figures 2A, B).

Similar differences in [Na$^+$]$_d$ were obtained in the measurements carried out in quiescent cardiomyocytes of Chagas-infected mice at different phases of infection. In cardiomyocytes from CONT mice [Na$^+$]$_d$ was 8 ± 0.2 mM; In cardiomyocytes from EAP-infected mice [Na$^+$]$_d$ was 9.4 ± 0.7 mM ($p$<0.001 compared to CONT cardiomyocytes); in cardiomyocytes from AP-infected mice [Na$^+$]$_d$ was 13.9 ± 0.8 mM ($p$<0.001 compared to CONT cardiomyocytes); and in cardiomyocytes from CP-infected mice [Na$^+$]$_d$ was 15.9 ± 1 mM ($p$<0.001 compared to CONT cardiomyocytes) (Figure 2C).
Removal of $[\text{Na}^+]_e$ Increased $[\text{Ca}^{2+}]_d$ in Cardiomyocytes

In a separate set of experiments, the reverse mode activity of NCX ($\text{Ca}^{2+}$ entry in exchange for $\text{Na}^+$ leaving the cell) was studied in quiescent cardiomyocytes isolated from control and infected mice by incubation in a solution in which $\text{Na}^+$ was replaced in equivalent amounts by NMG. $[\text{Ca}^{2+}]_d$ was measured before and after incubation with a low or $\text{Na}^+$ free solution. The
reduction of $[\text{Na}^+]_{\text{e}}$ to 65 mM caused an increase in $[\text{Ca}^{2+}]_{\text{d}}$ in CONT cardiomyocytes to 212 ± 27 nM, in cardiomyocytes from EAP-infected mice to 790 ± 62 nM, and cardiomyocytes from CP-infected mice to 1,320 ± 137 nM ($p < 0.001$ compared to cardiomyocytes from CONT, EAP, AP and CP-infected mice bathed in normal $[\text{Na}^+]_{\text{e}}$) (Figure 3).

Incubation in Na$^+$ free solution caused a further increase in $[\text{Ca}^{2+}]_{\text{d}}$ in control and cardiomyocytes from infected mice. In CONT cardiomyocytes $[\text{Ca}^{2+}]_{\text{d}}$ increased significantly to 309 ± 42 nM, in cardiomyocytes from EAP-infected mice to 540 ± 69 nM, from AP-infected mice to 1,016 ± 64 nM, and from CP-infected mice to 1,523 ± 62 nM respectively ($p < 0.001$ compared to cardiomyocytes from CONT, and EAP-, AP- and CP-infected mice bathed in normal $[\text{Na}^+]_{\text{e}}$). (Figure 3). The sustained increase $[\text{Ca}^{2+}]_{\text{d}}$ was maintained as long as Na$^+$ was absent from the bath solution and reversed when Na$^+$ was reintroduced into the Tyrode solution, except for cardiomyocytes from CP-infected mice where an irreversible elevation $[\text{Ca}^{2+}]_{\text{d}}$ associated with contracture was observed.

Removal of Extracellular Ca$^{2+}$ Prevents the Increase in $[\text{Ca}^{2+}]_{\text{d}}$ Induced by Na$^+$ Depletion
In a different set of experiments, we explored the contribution of the Ca$^{2+}$ influx to the elevation of $[\text{Ca}^{2+}]_{\text{d}}$ elicited by the withdrawal of Na$^+$ in quiescent cardiomyocytes from control and infected mice. Cardiomyocytes were incubated for 10 minutes in a Ca$^{2+}$-free solution prior to the withdrawal of Na$^+$ (see solutions). Incubation in a Ca$^{2+}$-free solution significantly reduced $[\text{Ca}^{2+}]_{\text{d}}$ to 98 ± 5 nM in cardiomyocytes from CONT mice ($p < 0.001$ compared to CONT cardiomyocytes in normal $[\text{Ca}^{2+}]_{\text{d}}$), to 100 ± 11 nM in cardiomyocytes from EAP-infected mice ($p < 0.001$ compared to CONT, AP and CP-infected mice bathed in normal $[\text{Na}^+]_{\text{e}}$) (Figure 4). Elevation of $[\text{Ca}^{2+}]_{\text{d}}$ induced by withdrawal of Na$^+$ was abolished in the absence of extracellular Ca$^{2+}$ in all cardiomyocyte groups (Figure 4).

Equilibrium Potentials
Using the Nernst equation and the actual values $[\text{Ca}^{2+}]_{\text{d}}$ and $[\text{Na}^+]_{\text{d}}$ found in the present study, the estimated $E_{\text{Ca}}$ in cardiomyocytes from CONT mice was +133 mV, in cardiomyocytes from EAP-infected mice was +127 mV, in cardiomyocytes from AP-infected mice was +119 mV, and in cardiomyocytes from CP-infected mice was +116 mV. While the estimated $E_{\text{Na}}$ in cardiomyocytes isolated from CONT mice was +74 mV, EAP-infected mice was +70 mV, AP-
infected mice was +59 mV, and CP-infected mice was +56 mV. The equilibrium potential of the Na+/Ca2+ exchanger (E_{NCX}) was -44 mV in cardiomyocytes from CONT, -46 mV from EA-infected mice, -61 mV from AP-infected mice, and -64 mV from CP-infected mice, respectively.

**KB-R7943 and YM-244769 Reduced [Ca^{2+}]_d and Prevented the Elevation of Ca^{2+} Induced by the Na+ Free Solution**

To determine the mechanisms involved in the elevation of [Ca^{2+}]_d caused by exposure to Na+ free medium, quiescent cardiomyocytes from control and infected mice were incubated in KB-R7943, a nonspecific blocker of the NCX reverse mode, which modified Na+ dependent binding (Iwamoto et al., 1996; Akabas, 2004). Cardiomyocyte preincubation with 10 μM KB-R7943 for 10 minutes significantly reduced [Ca^{2+}]_d and inhibited the increase in [Ca^{2+}]_d induced by the solution without Na+ (Figure 5A). KB-R7943 reduced [Ca^{2+}]_d to 152 ± 16 nM in cardiomyocytes from EAP-infected mice, to 186 ± 21 nM from AP-infected mice, and 258 ± 30 nM from CP-infected mice (Figure 5A). No significant effect was observed in cardiomyocytes from CONT mice (116 ± 5 nM). Preincubation with KB-R7943 prevented the elevation of [Ca^{2+}]_d caused by the Na+ free solution in cardiomyocytes of control and infected mice (compare Figures 3, 5A).

Due to the lack of specificity of KB-R7943 (Abramochkin and Vornanen, 2014), we also examined the effects of YM-244769, a high-affinity blocker of the NCX reverse mode (Iwamoto and Kita, 2006). Incubation with 1 μM YM-244769 for 10 minutes reduced [Ca^{2+}]_d to 176 ± 20 nM in cardiomyocytes from EAP-infected mice, to 254 ± 19 nM from AP-infected mice, and to 336 ± 32 nM from CP-infected mice. YM-244769 did not significantly reduce [Ca^{2+}]_d in cardiomyocytes of CONT and EAP-infected mice. YM-244769 fully inhibited the elevation of [Ca^{2+}]_d induced by the Na+ free solution in CONT cardiomyocytes and infected mice (compare Figures 3, 5B).

**DISCUSSION**

Cardiac alterations are a severe and recurrent complication related to Chagas disease and represent the most common causes of heart failure and sudden death in Latin America (Velasco and Morillo, 2020). The present study reinforces our previous finding that progressive deterioration of cardiac function in Chagas cardiomyopathy is associated with defective intracellular Ca^{2+} regulation. In this report, we demonstrate, for the first time, that ventricular cardiomyocytes from rodents infected with T. cruzi show a partial depolarization associated with aberrant [Ca^{2+}]_d and [Na^{+}]_d, which aggravates with endpoint after infection (chronic>acute>early acute). Furthermore, we provide evidence that chagasic infection enhances the reverse mode of NCX, causing an elevation of [Ca^{2+}]_d, which is not mediated by membrane depolarization.

Calcium is essential in the regulation of cardiac contractility, and defective intracellular Ca^{2+} homeostasis plays a vital role in the pathogenesis of diverse cardiac diseases (Houser and Margulies, 2003; Lopez et al., 2011; Uryash et al., 2021a; Uryash et al., 2021b). [Ca^{2+}]_d is regulated by several mechanisms that control Ca^{2+} influx-efflux and intracellular reuptake that allow the maintenance of [Ca^{2+}]_d within a physiological range (~100 nM) (Lopez et al., 2011; Mijares et al., 2014; Mijares et al., 2020). The [Ca^{2+}]_d values obtained from CONT cardiomyocytes are in agreement with previous estimates obtained from humans (Lopez et al., 2011; Mijares et al., 2020) and non-human ventricular myocytes (Mijares et al., 2014; Uryash et al., 2021a; Uryash et al., 2021b) using Ca^{2+}-selective microelectrodes and fluorescent Ca^{2+} indicator (Piacentino et al., 2003). The abnormal [Ca^{2+}]_d in cardiomyocytes from infected mice (chronic>acute>early acute) agree with a similar dysfunction observed in cardiomyocytes obtained from Chagas patients and could potentially promote arrhythmias, similar to those observed...

**FIGURE 5** | NCX blockers inhibited Na+ withdraw-induced [Ca^{2+}]_d increases in cardiomyocytes from control and Chagas infected mice. (A) Effects of KB-R7943 and (B) YM-244769 on [Ca^{2+}]_d increases caused by Na+ removal. [Ca^{2+}]_d was determined in (i) normal Tyrode solution (ii) after 10 min of incubation with 10 μM KB-R7943 or 1 μM YM-244769 and (iii) after incubation, either KB-R7943 in Na+ free solution or YM-244769 in Na+ free solution. Experiments were carried out in cardiomyocytes from CONT (n_{cells}=15-24 and n_{mice}=8), EAP (n_{cells}=12-19 and n_{mice}=6), AP (n_{cells}=13-21 and n_{mice}=8) and CP cardiomyocytes (n_{cells}=11-18 and n_{mice}=9). Data are expressed as mean ± S.E. Statistical analysis was performed as described above, "***p < 0.001. CONT: control mice; EAP: early acute phase of infected mice; AP: acute phase of infected mice; and CP: chronic phase of infected mice.
in patients with Chagas cardiomyopathy (Benziger et al., 2017; Almeida et al., 2018).

Normal resting [Na+]i in cardiomyocytes is in the range of 7-8 mM (Gray et al., 2001; Mijares et al., 2014), while in cardiomyocytes from infected mice, it was higher (CP>EP>AEP). Intracellular [Na+]i is mainly regulated in cardiac myocytes by Na+/K+-ATPase, Na+/Ca2+ exchange, Na+ channels, and amiloride-sensitive Na+/H+ exchanger (Everts et al., 1992; Blaustein and Lederer, 1999; Bers et al., 2003). An elevated [Na+]i, as found in Chagas-infected mice cardiomyocytes, could change the balance of fluxes through NCX to favor a greater inflow of Ca2+ (reverse mode) (Blaustein and Lederer, 1999), contributing to intracellular Ca2+ overload as observed in Chagas-infected mice cardiomyocytes. Furthermore, it is plausible that the partial depolarization observed in cardiomyocytes from infected mice (chronic>acute>early acute) may be related to diastolic Na+ overload. Unfortunately, we did not explore whether the elevation of [Na+]i in cardiomyocytes from infected mice was related to an increased influx or decreased efflux of Na+; therefore, no conclusions can be drawn.

Sodium-calcium exchange is the major Ca2+ efflux mechanism of ventricular cardiomyocytes. NCX mediates an electrogenic exchange of 3 Na+ for 1 Ca2+, which can occur in the forward (Ca2+-extrusion– Na+ entry) or in the reverse (Ca2+ entry– Na+ extrusion) mode (Blaustein and Lederer, 1999; Bers, 2000; Bers, 2002). In this study, we provide evidence for the first time of an enhancement in the reverse mode function of NCX in cardiomyocytes from infected mice (chronic>acute>early acute). The increase in [Ca2+]i mediated by NCX was not associated with membrane depolarization and was dependent on extracellular [Ca2+] and [Na+] in all cardiomyocytes. Therefore, changes in NCX could contribute to intracellular Ca2+ overload, but could also contribute to the arrhythmogenesis observed in Chagas patients (Stein et al. 2018). The elevation of [Ca2+]i was prevented in cardiomyocytes from control and infected mice by removing extracellular Ca2+ and reversed when Na+ was reintroduced into the bath, except for cardiomyocytes from CP-infected mice, where the removal of Na+ (partially or completely) produced irreversible contraction and cell death (40% in 65 mM [Na+]i and 82% in Na+ free solution, respectively).

The mode in which NCX operates is dependent on the Na+ and Ca2+ gradients across the sarcolemma, as well as the membrane potential, following a driving force equal to \( E_m - E_{Na/Ca} \) (where \( E_{Na/Ca} = 3E_{Na} - 2E_{Ca} \) with \( E_{Na} \) and \( E_{Ca} \) represent the equilibrium potentials of Na+ and Ca2+, respectively) (Bers and Ginsburg, 2007). If the driving force for 3Na+ is greater than 1Ca2+ in the cell (3:1 Na+/Ca2+ stoichiometry), the NCX will transport Na+ into the cell and take Ca2+ out (forward mode). On the other hand, if under another set of conditions (altered membrane potential, ionic gradients, or post-translational modifications), the driving force for 3Na+ is less than that for 1Ca2+ in the cell, then the electrochemical gradient of Ca2+ will become the dominant inward driving force (reverse mode) (Bers and Ginsburg, 2007). The intracellular ionic changes in cardiomyocytes from infected mice modified the driving force \( (E_m - E_{Na/CA}) \) by 5 mV in cardiomyocytes from EAP-infected mice, 22 mV in cardiomyocytes from AP-infected mice, and 29 mV in cardiomyocytes from CP-infected mice.

KB-R7943 significantly reduced [Ca2+]i by 1.3 times in cardiomyocytes from EAP-infected mice, 1.7 times in AP-infected mice, and 1.8 times in CP-infected mice, suggesting that the elevation of [Ca2+]i observed in cardiomyocytes of Chagas infected mice was due in part to an influx of Ca2+ mediated by NCX in its reverse mode. On the contrary, in cardiomyocytes from CONT mice, KB-R7943 did not modify [Ca2+]i, indicating that in healthy quiescent cardiomyocytes, NCX in its reverse mode does not contribute significantly to [Ca2+]i. Furthermore, KB-R7943 prevented the elevation of [Ca2+]i induced by Na+ withdrawal in cardiomyocytes from CONT and cardiomyocytes from infected mice. The involvement of NCX in the pathophysiology of Chagas disease is consistent with the recent publication by Santos-Miranda et al. (Santos-Miranda et al., 2021), which found the contribution of NCX as a cellular arrhythmogenic substrate in isolated cardiomyocytes from infected mice with the Colombian strain of T. cruzi. However, the effect of KB-R7943 on [Ca2+]i must be considered with caution due to the lack of selectivity, since the NCX blocker also affects voltage-gated Na+ and Ca2+ channels, inward rectifying K+ channels in cardiac cells (Watanabe et al., 1996).

YM-244769 is a potent and highly selective NCX blocker that up to 1 µM (dose used in the present study) preferentially inhibits the reverse mode of NCX, with no effect on the forward mode (Iwamoto and Kita, 2006). YM-244769 significantly reduced [Ca2+]i by 1.3 times in cardiomyocytes from AP- and 1.4 times from CP-infected mice. YM-244769 did not significantly reduce [Ca2+]i in cardiomyocytes from CONT and EAP-infected mice, suggesting that the contribution of NCX to [Ca2+]i is negligible. The effect of YM-244769 on [Ca2+]i cardiomyocytes was small compared to KB-R7943, which is consistent with the fact that YM-244769 is a more specific NCX blocker and that KB-R7943 can act on other Ca2+ entry pathways. Furthermore, YM-244769 blocked the observed elevation of [Ca2+]i caused by the Na+ free solution in all cardiomyocytes. Together, these data strongly support the hypothesis that Ca2+ entry mediated by the reverse NCX mode plays a significant role in [Ca2+]i dyshomeostasis observed in cardiomyocytes isolated from Chagas infected mice during acute and chronic stages of infection. The fact that KB-R7943 or YM-244769 did not normalize [Ca2+]i in cardiomyocytes from infected mice suggests the existence of additional Ca2+ pathways that appear to be altered due to Chagas infection.

**Conclusions**

These results provide, for the first time, evidence that NCX plays an important role in aberrant diastolic [Ca2+]i observed in cardiomyocytes from infected mice (chronic>acute>early acute). These novel findings may open a new therapeutic approach to improve cardiac function in patients suffering from chronic Chagas cardiomyopathy because there is still no effective treatment. Unfortunately, Chagas cardiomyopathy remains largely ignored despite its medical and social relevance.
**Study Limitations**

Despite the novelty of this study, some limitations should be pointed out. We did not determine whether the elevation of $[Na^+]_i$ in cardiomyocytes from infected mice could be related to an increased influx or decreased efflux of Na$^+$. Furthermore, the expression of NCX and other proteins involved in intracellular Ca$^{2+}$ regulation were not studied.

**ACKNOWLEDGMENTS**

The author thanks Dr. Jose O’Daly for kindly giving us the *T. cruzi*-infected mice.

**AUTHOR CONTRIBUTIONS**

JRL: Designed research, performed the experiments, and analyzed the data; NL: Performed the experiments; JAA: Designed research, and analyzed the data. All authors contributed to manuscript revision, read, and approved the submitted version.
