(Dated: October 25, 2011)

The transmission of a probe field experiencing electromagnetically induced transparency and optical switching in an atomic medium enclosed in an optical cavity is investigated. Using a semiclassical input-output theory for the interaction between an ensemble of four-level atoms and three optical cavity fields coupled to the same spatial cavity mode, we derive the steady-state transmission spectra of the probe field and discuss the dynamics of the intracavity field buildup. The analytical and numerical results are in good agreement with recent experiments with ion Coulomb crystals [M. Albert et al., Nature Photon. 5, 633 (2011)].

I. INTRODUCTION

Electromagnetically Induced Transparency (EIT) is a quantum interference phenomenon occurring when two electromagnetic fields resonantly excite two different transitions sharing a common state $|1\rangle$. An intense control field addressing one of the transitions can substantially modify the linear dispersion and absorption of an atomic medium for a weak probe field resonant with the second transition. Since its first observation by Boller et al. [4], EIT has been successfully exploited for instance to control the propagation of light pulses through an otherwise opaque medium for light storage and retrieval [5–12] and quantum memories [13–22]. Besides providing a means for controlling the linear susceptibility of an atomic medium EIT can also be exploited for generating strong optical nonlinearities [2, 3, 23, 24]. For instance, in the four-level atomic configuration such as the one depicted in Fig. 1b, the nonlinear susceptibility of the medium can be strongly enhanced at the same time as the linear susceptibility is suppressed. The large cross-Kerr effect between the probe field and a third switching field can then be used e.g. for high-efficiency photon counting [27], all-optical switching [26, 27] and nonlinear optics at low-light levels [2, 3, 24, 28, 29], nonclassical state generation [30] or the realization of strongly interacting photon gases [31, 32].

When such a nonlinear EIT medium is positioned in an optical cavity one first-of-all benefits from the enhanced interaction of the ensemble with well-defined spatio-temporal field modes. This is of great value for enhancing the effective optical depth and for realizing high-efficiency quantum memories [33, 36] or Fock state quantum filters [37]. The EIT-induced reduction of the cavity linewidth [38] can also be used to increase the sensitivity of atomic magnetometers [7, 39]. enhance cavity optomechanical cooling processes [40–42], achieve lasing without inversion [43], optical switching [44, 45] or quantum state swapping [46].

On the other hand, the cavity EIT-interaction can be furthermore exploited to enhance the cross-Kerr nonlinearity to investigate e.g. photon-blockade mechanisms [47, 49], photon-photon interactions [50], highly-entangled state generation [51] or novel quantum phase transitions for light [52].

Cavity EIT has been observed with atomic beams [53], in cold and room temperature atomic ensembles [54–56], and even with single or few atoms in high-finesse optical cavities [57, 58]. Cavity EIT as well as EIT-based optical switching have also recently been observed with cold ion Coulomb crystals [59].

We theoretically investigate here the interaction between an ensemble of atoms with the four-level structure depicted in Fig. 1 and three optical fields coupled to the same spatial cavity mode. Using a semiclassical input-output theory we derive the atomic linear and nonlinear susceptibilities for the probe field and its steady state transmission spectra as it experiences EIT or an EIT-based cross-Kerr effect. We study in particular the effect of the transverse mode profiles of the fields on the normal mode spectrum of the atom-cavity system as in the experiments of Ref. [51] and compare with the more usual situation where only the probe field is coupled to the cavity [53–58].

The paper is organized as follows: in Sec. II we introduce the system under consideration and derive the equations of motion. We obtain the probe field susceptibility and transmission spectrum, first when the probe and control fields interact with the atoms in an EIT situation in Sec. III then when all three cavity fields interact simultaneously with the atomic medium in Sec. IV. Finally, all-optical switching at low-light levels using ion Coulomb crystals as in the experiments of Ref. [59] is discussed in Sec. V.

II. SYSTEM CONSIDERED AND EQUATIONS OF MOTION

We consider an ensemble of $N_{tot}$ four-level atoms with the level structure depicted in Fig. 1 where levels $|1\rangle$
and $|2⟩$ are long-lived ground or metastable states, and levels $|3⟩$ and $|4⟩$ are excited states. The atoms are enclosed in a linear optical cavity where they interact with three optical fields: a probe field on the $|1⟩ → |3⟩$ transition, a control field on the $|2⟩ → |3⟩$ transition and a switching field on the $|2⟩ → |4⟩$ transition. The cavity is assumed to have asymmetric mirror transmissions, $T_H$ and $T_L$, with $T_H \gg T_L$, and, unless stated otherwise, all fields are injected into the cavity through the high-transmission mirror. The annihilation operators of the field modes in the Heisenberg picture and in the rotating frame are denoted by $a_p$, $a_c$ and $a_s$, respectively, with the convention $[a_α, a_β^†] = 1, \ (α = p, c, s)$. $\sigma_{μν} = |μ⟩⟨ν|$ is the atomic operator associated with the $j$-th ion positioned at $r_j \ (μ, ν = 1 − 4)$. We assume that all three fields are resonant or close to a resonance with the same spatial cavity mode, which we take to be the fundamental Gaussian TEM$_{00}$ mode for simplicity. The interaction Hamiltonian in the rotating-wave approximation and in the rotating frame is

$$H_{af} = -\hbar \sum_j \bar{g}_p \Psi_p (r_j) \cos[k_p z_j + \varphi_p (r_j)] \hat{a}_p \hat{σ}_{j1}^{(j)} \quad (1)$$

$$-\hbar \sum_j \bar{g}_c \Psi_c (r_j) \cos[k_c z_j + \varphi_c (r_j)] \hat{a}_c \hat{σ}_{j2}^{(j)}$$

$$-\hbar \sum_j \bar{g}_s \Psi_s (r_j) \cos[k_s z_j + \varphi_s (r_j)] \hat{a}_s \hat{σ}_{j2}^{(j)} + \text{h.c.},$$

where the $\bar{g}$'s are the maximal single-atom coupling strengths for the transitions considered, the $Ψ$'s and $\varphi$'s are the fields’ transverse mode functions and longitudinal mode phases, respectively [60]. Since our main goal is to discuss the effects related to the spatial transverse structure of the fields we will consider for simplicity the situation where the length, $2L$, of the ensemble is much smaller than the Rayleigh range of the cavity, as e.g. in the experiments of Ref. [59]. We thus neglect the longitudinal variations of the phases and the waists of the light fields over the length of the ensemble. We therefore set the longitudinal mode phases to 0 and assume a Gaussian transverse structure of the fields given by $Ψ_α (r) = \exp(-r^2 / w_α^2) \ (α = p, c, s)$, where $w_α$ is the cavity waist considered. We will in the following examine two situations:

(i) The novel case in which all three fields have the same transverse mode profile and the ensemble has a large radial extension as compared to the waists, like e.g. in the experiments of [59]. We shall refer to this situation as the all-cavity case.

(ii) The more usual situation in which the control and switching fields have a large transverse intensity profile as compared to the extension of the ensemble. This would typically be the case if these fields were interacting with the atoms not through the cavity [54–58], or for an ensemble radially confined to a region with dimension much smaller than the waists, as could be obtained with e.g. a string of atoms or two-component ion Coulomb crystals [61]. We shall refer to such a situation, in which the transverse mode profiles of the fields can be ignored, as the standard case.

We will in addition assume that, because of their motion, the atoms are “warm” enough such that they probe any field variation along the longitudinal standing-wave structures of the fields during the characteristic time scales of the dynamics of the fields due their interactions with the atoms. As discussed e.g. in [62–65] and in Appendix A, one can under these conditions assume averaged longitudinal couplings $\bar{g}_α = g_α / \sqrt{2} \ (α = p, c, s)$. Keeping only the transverse spatial dependence of the cavity modes, the Hamiltonian becomes

$$H_{af} = -\hbar \sum_j \bar{g}_p \Psi_p (r_j) \hat{σ}_{j1}^{(j)} + \bar{g}_c \Psi_c (r_j) \hat{σ}_{j2}^{(j)}$$

$$+ \bar{g}_s \Psi_s (r_j) \hat{σ}_{j2}^{(j)} + \text{h.c.} \quad (2)$$

For comparison the ”cold” atom situation where the atoms are well-localized with respect to the field standing-wave structures during the interaction is treated in Appendix A.

The atom-field dynamics of the observable mean values can be standardly derived via $\hat{o} = (1/\hbar)⟨[\hat{o}, H]⟩$, where $o \equiv ⟨\hat{o}⟩$ is the mean value of observable $\hat{o}$ and the total Hamiltonian $H = H_a + H_f + H_{af}$ is the sum of the interaction Hamiltonian [29] and of the atomic and field Hamiltonians

$$H_a = -\hbar \sum_j (\Delta_p - \Delta_c)\hat{σ}_{j3}^{(j)} + (\Delta_p - \Delta_s)\hat{σ}_{j2}^{(j)} + (Δ_ρ - Δ_c + Δ_s)\hat{σ}_{j4}^{(j)},$$

$$H_f = -\hbar \Delta'_p \hat{σ}_{j1}^{(j)} + \hbar \Delta'_c \hat{σ}_{j1}^{(j)} - \hbar \Delta'_s \hat{σ}_{j1}^{(j)},$$

$$H_{af} = -\hbar \sum_j \Delta'_p \hat{σ}_{j3}^{(j)} + (Δ_p - Δ_c)\hat{σ}_{j2}^{(j)} + (Δ_p - Δ_c + Δ_s)\hat{σ}_{j4}^{(j)},$$

where $Δ_p = ω_p - ω_{31}$, $Δ_c = ω_c - ω_{32}$ and $Δ_s = ω_s - ω_{32}$ are the one-photon detunings, and $Δ'_p = ω_p - ω_{1p}$ are the cavity detunings between the fields with frequency $ω_{1p}$ and the cavity resonance frequency $ω_{cav} (α = p, c, s)$. Denoting by $γ_{31}$, $γ_{32}$ and $γ_{42}$ the spontaneous decay rates and introducing a phenomenological decay rate
$\gamma_0$ for the ground-state coherence operators $\sigma^{(j)}_{12} (\gamma_0 \ll \gamma_{31}, \gamma_{32}, \gamma_{42})$, one obtains the following set of coupled differential equations

$$
\dot{\sigma}^{(j)}_{12} = -\gamma_0 - i(\Delta_p - \Delta_c)\sigma^{(j)}_{12} - i\bar{g}_p\psi_p(r_j)a_p\sigma^{(j)}_{32} + i\bar{g}_c\psi_c(r_j)a^*_c\sigma^{(j)}_{13} + i\bar{g}_s\psi_s(r_j)a_s\sigma^{(j)}_{14}
$$

$$
\dot{\sigma}^{(j)}_{13} = -(\gamma - i\Delta_p)\sigma^{(j)}_{13} + i\bar{g}_p\psi_p(r_j)a_p\sigma^{(j)}_{14} - i\bar{g}_c\psi_c(r_j)a_c\sigma^{(j)}_{12} + i\bar{g}_s\psi_s(r_j)a_s\sigma^{(j)}_{14}
$$

$$
\dot{\sigma}^{(j)}_{14} = -(\gamma - i\Delta_p)\sigma^{(j)}_{14} + i\bar{g}_p\psi_p(r_j)a_p\sigma^{(j)}_{13} + i\bar{g}_c\psi_c(r_j)a_c\sigma^{(j)}_{12} - i\bar{g}_s\psi_s(r_j)a_s\sigma^{(j)}_{12}
$$

$$
\dot{\sigma}^{(j)}_{23} = -(\gamma - i\Delta_c)\sigma^{(j)}_{23} + i\bar{g}_c\psi_c(r_j)a_c\sigma^{(j)}_{24} + i\bar{g}_s\psi_s(r_j)a_s\sigma^{(j)}_{24}
$$

$$
\dot{\sigma}^{(j)}_{24} = -(\gamma - i\Delta_c)\sigma^{(j)}_{24} - i\bar{g}_c\psi_c(r_j)a_c\sigma^{(j)}_{23} + i\bar{g}_s\psi_s(r_j)a_s\sigma^{(j)}_{23}
$$

where $\gamma = (\gamma_{31} + \gamma_{32})/2 + \gamma_0$, $\gamma_c = \gamma_{42}/2 + \gamma_0$ and $\tau$ is the cavity round-trip time. The input fields are denoted by $a_{\alpha}^{(in)}$ ($\alpha = p, c, s$). The total cavity field decay rate (assumed equal for all fields for simplicity) is denoted by $\kappa = \kappa_H + \kappa_c + \kappa_A$, where $\kappa_H, L = T_{H, L}/2\tau$ are the decay rates corresponding to the mirrors’ transmission and $\kappa_A = A/2\tau$ is a decay rate corresponding to round-trip absorption losses $A$. While these absorption losses are not essential to the understanding of the physical mechanisms studied here, we include them for completeness as they very often affect experiments with high-finesse cavities $^{57,58}$.

The previous set of equations can be solved numerically for any initial internal atomic state, input field pulses, ensemble geometry and atomic distribution. We focus in the following on the situation in which all the atoms are in state $|1\rangle$ initially and the probe field is much weaker than the control and switching fields, so that one can perform a first-order expansion in the probe field to get analytical expressions for various quantities, such as the probe susceptibility, its cavity transmission and reflection, the EIT buildup time, etc.

### III. CAVITY ELECTROMAGNETICALLY INDUCED TRANSPARENCY

#### A. EIT regime

We first investigate the EIT situation where the atoms interact with both the probe and control fields, but no switching field is injected into the cavity. The input probe and control fields are abruptly switched on at time $t = 0$ and have thereafter constant intensities. We place ourselves in the weak probe regime, when $g_p|a_p| \ll g_c|a_c|$ and the intracavity photon number is much smaller than the number of interacting atoms. All the atoms are then essentially in $|1\rangle$, and the only non-zero atomic components at first order are the probe optical dipole $\sigma^{(j)}_{13}$ and the ground-state coherence $\sigma^{(j)}_{12}$. We also assume that the control field is tuned to resonance with the $|2\rangle \rightarrow |3\rangle$ transition ($\Delta_c = 0$) and the cavity is resonant with the $|2\rangle \rightarrow |3\rangle$ transition, i.e. $\Delta_p = \Delta_c = \delta = \Delta$. As the control field probes no atom, its intracavity amplitude reaches its steady state value in a time $\kappa_c^{-1}$. Since we are interested in getting simple analytical expressions for the steady state of the system and its dynamics over the typically slower EIT buildup timescales, we can consider that the control field intracavity Rabi frequency is constant and equal to its steady state value $\Omega_c = \bar{g}_c a_c$.
Equivalently, the control field can be turned on slightly before the probe pulse is applied. The relevant equations of motion governing the evolution of the intracavity probe field are then

\[
\dot{a}_p = -(\kappa - i\Delta)a_p + ig_p \sum_j \Psi_p(r_j)\sigma_j^{(j)} + \sqrt{2\kappa_H / \tau a_p^{in}},
\]

\[
\dot{\sigma}_{13}^{(j)} = - (\gamma - i\Delta)\sigma_{13}^{(j)} + ig_p \Psi_p(r_j) a_p + i\Omega_c \Psi_c(r_j)\sigma_{12}^{(j)},
\]

\[
\dot{\sigma}_{12}^{(j)} = - (\gamma_0 - i\Delta)\sigma_{12}^{(j)} + i\Omega_c \Psi_c(r_j)\sigma_{13}^{(j)}.
\]

### B. Steady state susceptibility

These equations can be readily solved in steady state to obtain the mean value of the intracavity probe field,

\[
a_p = \frac{\sqrt{2\kappa_H / \tau a_p^{in}}}{\kappa - i\Delta - i\chi_{EIT}},
\]

where the EIT susceptibility is given by

\[
\chi_{EIT} = \sum_j \frac{ig_p^2 \Psi_p^2(r_j)}{\gamma - i\Delta + \frac{1}{2}g_p^2 / \gamma - i\Delta} e^{-2\gamma^2 / w^2}.
\]

For large ensembles of atoms with non-correlated positions, we can reformulate Eq. (21) in terms of the local atomic density \(\rho(r)\). Assuming the same transverse profiles for the control and probe fields \(\Psi_p(r) = \Psi_c(r) = \exp(-r^2 / w^2)\), Eq. (21) can then be recast in

\[
\chi_{EIT} = \frac{ig_p^2 N}{2} \int_V d\rho(r) \frac{e^{-2\gamma^2 / w^2}}{\gamma - i\Delta + \frac{1}{2}g_p^2 / \gamma - i\Delta} e^{-2\gamma^2 / w^2},
\]

where \(\Omega_c = g_c|a_c|\). For an ensemble with a uniform atomic density, such as ion Coulomb crystals in a linear radiofrequency trap as used in \([55, 66-68]\), and with a large radial extension as compared to the cavity waist (see e.g. \([59, 66, 68]\)), the integral can be calculated analytically and yields a susceptibility

\[
\chi_{EIT} = \frac{ig_p^2 N}{\gamma - i\Delta} \ln(1 + \Theta),
\]

where

\[
\Theta = \frac{\Omega_c^2 / 2}{(\gamma - i\Delta)(\gamma_0 - i\Delta)}
\]

is an effective saturation parameter for the two-photon transition and \(N = \frac{\rho^2 N}{2} L\) is the effective number of atoms defined in \([66, 68]\). This result can be compared to the standard situation in which the control field waist is much larger than that of the probe field \([1, 3, 69]\)

\[
\chi_{EIT} = \frac{ig_p^2 N}{\gamma - i\Delta} \frac{1}{1 + \Theta}
\]

![FIG. 2. (Color online) Real (blue) and imaginary (red) parts of the probe first-order susceptibility as a function of the probe detuning \(\Delta\) (solid line: all-cavity EIT [Eq. (25)], dashed line: standard EIT [Eq. (23)]). The parameters, \((g_p\sqrt{N}, \gamma, \gamma_0, \Omega_c) = 2\pi \times (16, 11.2, 6 \times 10^{-4}, 6)\) MHz, are similar to those used in the experiments of Ref. \([55, 69]\).](image)

The real and imaginary part of these susceptibilities are plotted in Fig. 2 for typical parameters used in the experiments with ion Coulomb crystals of \([59]\). They show the typical transparency window in the absorption profile and the rapid change in dispersion around two-photon resonance. In comparison with the standard one, the all-cavity susceptibility clearly shows non-Lorentzian lineshapes, as expected from its different dependence with respect to \(\Theta\) Eq. (23 and 25).

From Eq. (20) and the input-output relations

\[
a_p^{ref} = \sqrt{2\kappa_H / \tau a_p^{in}}, \quad a_p^{tr} = \sqrt{2\kappa_L / \tau a_p},
\]

the steady state cavity transmission and reflection for the probe field are given by

\[
T = \left| \frac{a_p^{tr}}{a_p^{in}} \right|^2 = \left| \frac{2\sqrt{\kappa_H \kappa_L}}{\kappa_H + \kappa_L + \kappa_A - i\Delta - i\chi} \right|^2,
\]

\[
R = \left| \frac{a_p^{ref}}{a_p^{in}} \right|^2 = \left| \frac{2\sqrt{\kappa_H \kappa_L}}{\kappa_H + \kappa_L + \kappa_A - i\Delta - i\chi} \right|^2.
\]

Using Eqs. (23, 25) one can then compute the normal mode spectrum of the probe field transmission. In the collective strong coupling regime, when \(g_p\sqrt{N} > \kappa, \gamma\), one expects three normal modes in the transmission spectrum: two modes at probe detunings \(\pm \sqrt{g_p^2 N + \Omega_c^2 / 2}\), corresponding to the two-level ensemble modes \(\pm g_p\sqrt{N}\) shifted by the presence of the control field, and one mode at zero-detuning for the probe (two-photon resonance here), corresponding to the cavity EIT resonance \([53, 69]\).

This is illustrated in Fig. 3 where the probe transmission spectra, normalized to the bare cavity resonant value

\[
T_0 = \left| \frac{\kappa}{\kappa - i\Delta - i\chi} \right|^2
\]
In the standard case and in the regime considered previously ($\gamma_0 \ll \Omega_c^2 \ll g_p^2 N$), one finds that the probe transmission is Lorentzian-shaped around $\Delta = 0$ (see e.g. [3, 38])

$$T \propto \left| \frac{1}{\kappa + \gamma_0 g_p^2 N/2} - i\Delta \frac{g_p^2 N}{2\Omega_c^2} \right|^2 \propto \frac{1}{|\kappa_{EIT} - i\Delta|^2} \quad (30)$$

The interaction thus emulates a cavity with an effective halfwidth

$$\kappa_{EIT} = \gamma_0 + \kappa \frac{\Omega_c^2/2}{g_p^2 N} \quad (31)$$

which is smaller than the bare cavity halfwidth $\kappa$ when $g_p \sqrt{N} \gg \Omega_c$. The analysis is a bit more complicated in the all-cavity case, due to the complex dependence of the susceptibility with the saturation parameter $\Theta$ and the non-Lorentzian profile (as can be seen e.g. from Fig. 3). The different dependence of the susceptibility with the effective saturation parameter $\Theta$ makes it in general impossible to define an effective control field Rabi frequency in the all-cavity situation which would give the same susceptibility or transmission as in the standard case. However, if one is interested in comparing situations in which the EIT resonance features have similar widths, one can perform a similar expansion of the normalized transmission given by Eqs. (28) and (29) around $\Delta = 0$ and define an EIT resonance width also in the all-cavity situation. In the regime $\Omega_c^2 \gg \gamma_0$, the all-cavity EIT resonance width matches the standard EIT one with an effective control field Rabi frequency $\Omega_{c,eff} \approx \Omega_c/[(\sqrt{2\pi^2 + 4(\ln 2C)^2} - \pi)/(\pi^2/2 + 2(\ln 2C)^2)]^{1/2}$, where $C = g_p^2/2\kappa\gamma$. For the parameters of Fig. 3, the scaling factor for the effective Rabi frequency is $\sim 2.2$ for instance. On the other hand, if one was interested in comparing the minimum absorption level on two-photon resonance, one could define an effective control Rabi frequency as $\Omega_{c,eff} \sim \Omega_c/[(\ln(\Omega_c^2/\gamma_0))^{1/2}]$, in the EIT regime where $\Omega_c^2 \gg \gamma_0$ and for a given value of $\Omega_c$. The resonant absorption in the all-cavity situation with a control field Rabi frequency $\Omega_c$ could then be effectively compared to that of a standard situation in which the maximal Rabi frequency has been scaled by a factor $\sim (\ln(\Omega_c^2/\gamma_0))^{1/2}$.

Fig. 3 shows the corresponding reflectivity spectra for a cavity having non negligible roundtrip absorption losses, as observed in the experiments of [50]. In general, since the reflected field results from the interference between the input field and the intracavity field, the reflectivity levels have a slightly more complex dependence on the atomic absorption and the cavity losses. The reflectivity spectrum exhibits nonetheless the same qualitative features as the transmission, with two normal modes at frequencies $\pm \sqrt{g_p^2 N + \Omega_c^2/2}$ and a third one at zero two-photon detuning corresponding to the reduction of atomic absorption due to the EIT effect. Effective con-

![Graph](image-url)
C. Dynamics

In this section we focus on the dynamics towards reaching the steady state during a resonant EIT interaction ($\Delta = 0$). Assuming again a constant control field Rabi frequency and performing a Laplace transform of Eqs. (17), (18) and (19) yields the following equations

$$(\kappa + s)a_p[s] = i \sum_j \hat{g}_p \Psi_p(r_j) \sigma_{12}^{(j)}[s] + \sqrt{\frac{2\kappa_H}{\tau}} a_p^{in}[s]$$

$$(\gamma + s)\sigma_{12}^{(j)}[s] = i\hat{g}_p \Psi_p(r_j) a_p[s] + i\bar{\Omega}_c \Psi_c(r_j) \sigma_{13}^{(j)}[s]$$

$$(\gamma_0 + s)\sigma_{13}^{(j)}[s] = i\bar{\Omega}_c^* \Psi_c(r_j) \sigma_{12}^{(j)}[s]$$

where the Laplace transform of $f$ is defined by

$$f[s] = \mathcal{L}[f(t)] = \int_0^\infty dt \ e^{-st} f(t)$$

and we have assumed the initial conditions $a_p(0) = \sigma_{12}^{(j)}(0) = \sigma_{13}^{(j)}(0) = 0$. These equations allow for extracting the Laplace transform of the intracavity probe field amplitude

$$a_p[s] = \frac{\sqrt{2\kappa_H/\tau} a_p^{in}[s]}{\kappa + s + \sum_j \gamma + s + |\bar{\Omega}_c|^2/(\gamma_0 + s)}$$

and calculate its time evolution by performing the inverse Laplace transform. It is however instructing to look at the dynamics in the adiabatic limit in which the effective cavity linewidth emulated by the EIT medium is smaller than the bare cavity linewidth and the dipole decay rate, i.e. $\kappa_{EIT} < \kappa, \gamma$. In this limit it can be shown that the intracavity field and the optical coherence adiabatically both follow the ground state coherence, which evolves at a rate $\kappa_{EIT}$. In the standard case, from Eq. (33), one finds that the intracavity field amplitude increases exponentially with a time constant $1/\kappa_{EIT}$, consistently with the steady state spectrum analysis of the previous section. In the all-cavity case the inverse Laplace transform has to be calculated numerically. It yields a non-exponential increase in the intracavity field intensity occurring on a timescale approximately given by $1/\kappa_{EIT}$, with $\bar{\Omega}_c$ scaled as in the previous section.

IV. OPTICAL SWITCHING

We now turn to the all-optical switching situation, in which the transition $\ket{2} \leftrightarrow \ket{4}$ is addressed by the
switching field $\hat{a}_s$, while the control and probe fields are in an EIT situation. When the switching field is detuned from atomic resonance ($|\Delta_s| \geq \gamma_s$) and weak enough such that the absorption to level 4 is negligible, its main effect is to light-shift level 2, thereby changing the bare EIT resonance condition for the control and probe fields. When the light-shift becomes comparable or greater than the width of the cavity EIT window, the transmission of the probe field is inhibited, as the cavity is switched off resonance by the presence of the switching field.

A. Probe susceptibility

The real and imaginary part of both susceptibilities are shown in Fig. 6 for typical parameter values taken from [53]. As expected, in the standard case, the effect of the switching field is to shift the position of the EIT resonance by an amount that corresponds to the AC Stark shift of level 2. The effect is more complex in the all-cavity case, as the shift for each atom depends on its radial position, thus leading to an asymmetric frequency behavior of the absorption and dispersion around two-photon resonance. These effects are manifest on the probe field transmission spectra, which are shown in Fig. 7 for different switching field intensities. While, in the standard configuration, the probe transmission profile is shifted away from the bare two-photon resonance without too much distortion as the switching field intensity increases, it is substantially distorted in the all-cavity case due to the different AC Stark shifts experienced by atoms at different radial positions. The accuracy of these analytical expressions for the susceptibility and transmission have been checked by numerically solving Eqs. (4)-(10). These findings are also in good agreement with the experimental observations of Ref. [59].

V. LOW-LIGHT LEVEL OPTICAL SWITCHING WITH ION COULOMB CRYSTALS IN CAVITIES

We now turn to the prospects of achieving low-light optical switching of a single-photon probe field using ion Coulomb crystals in an optical cavity and base our practical discussion on the parameters of Refs. [54, 60]. We assume an asymmetric linear cavity geometry similar to that described in [53], with length $\sim 1$ cm and finesse $\sim 4000$ and $\kappa \sim \kappa_H = (2\pi)1.5$ MHz. We consider an interaction with $^{40}\text{Ca}^+$ ions on the $3d^3D_{3/2}, m_J = +3/2 \rightarrow$
4p 2P_{1/2}, m_J = +1/2 (probe), 3d 3D_{3/2}, m_J = -1/2 \rightarrow 4p 2P_{1/2}, m_J = +1/2 (control) and 3d 3D_{3/2}, m_J = -1/2 \rightarrow 4p 2P_{3/2}, m_J = +1/2 (switching) transitions, for which the respective maximal ion coupling strength are \((g_p, g_c, g_s) = (2\pi) \times (0.53, 0.22, 0.18)\) MHz respectively. We assume a standard situation and numerically calculate the steady state normalized probe transmission by solving Eqs. 4-10 for a probe input field intensity such that the mean intracavity photon number is one in steady state in an empty resonant cavity.

Taking an effective collective coupling strength \(g\sqrt{N} = (2\pi)16\) MHz renders the crystal/cavity system completely opaque for the probe field in the absence of control field \((T_0 \sim 1\%\). We assume that the cavity field decay rate is the same for all fields and that the atomic decay rates as defined in 4-15 are \((\gamma, \gamma_s, \gamma_0) = (2\pi) \times (11.2, 11, 6 \times 10^{-4})\) MHz. For the simulations the control and switching fields are injected 0.5 \(\mu\)s before the probe field, with rise times much shorter than the inverse of the cavity field decay rate, to allow them for reaching their steady state values. The mean intracavity probe photon number is then calculated in steady state, yielding the cavity transmission. Using a control field Rabi frequency \(\Omega_c = (2\pi)2\) MHz allows for increasing the resonant probe transmission to \(~90\%\). The variation of the probe transmission for different switching field detunings \(\Delta_s\) and intracavity photon numbers \(n_s\) is shown in Fig. 8 under these conditions. For all these simulations we checked that the absorption of photons to level [4] was negligible and that the depletion of atoms from level [1] remained at most at the percent level. Optical switching is observed to take place with increasing photon numbers as the detuning is increased, as expected from the previous discussion and analysis. We define the minimal switching photon number \(n_s^*\) as the minimal number of intracavity switching photons needed to bring the normalized transmission from 90% to 10%. In the standard situation, one can easily show from 25 and 26 that having a 90% transmission in EIT imposes that \(\kappa_{EIT} \lesssim 40\gamma_0\). To get substantial switching we require that the light-shift induced by the switching field \(\Omega_s^2/2\Delta_s\) is a few times the width of the EIT transparency window \(\kappa_{EIT}\). A numerical estimation shows that \(\Omega_s^2/2\Delta_s \sim 5\kappa_{EIT}\), which gives \(n_s^* \sim 400\gamma_0\Delta_s/g_s^2\). In agreement with Fig. 8, we find that \(~17000\) photons are needed for the large detuning of 4.3 GHz used in 59 and \(~400\) for a detuning of \(~10\gamma_s\). The previous estimate is actually still valid for a resonant switching field replacing \(\Delta_s\) by \(\gamma_s\), which would give a minimal photon number of \(~40\) for the parameters of Fig. 8. This illustrative numerical example is based on the experimental parameters of 59, but we note that lower switching numbers could in principle be reached e.g. using smaller cavities or stronger switching transitions.
VI. CONCLUSION

Using a semiclassical theory for the interaction of four-level atoms with three optical cavity fields, the effect of the transverse mode profiles on the susceptibility and transmission spectrum of a probe field experiencing EIT or EIT-based optical switching has been discussed. Contrarily to the standard situation where the control switching field Rabi frequencies are the same for all atoms, non-Lorentzian EIT resonance lineshapes and asymmetrical switching lineshapes are predicted when all three fields are coupled to the same cavity mode. Closed analytical forms for the susceptibility and transmission spectrum of the probe field have been found to explain these lineshapes, in good agreement with numerical simulations and with experiments using ion Coulomb crystals in cavities. Last, the prospect for achieving these lineshapes, in good agreement with numerical

Appendix A: "Localized" or "delocalized" atom situations

In this section we investigate the effect of the atomic motion on the cavity EIT feature. Free-space EIT with standing-wave field geometries has been investigated both theoretically [62, 63, 65, 71, 72] and experimentally [12, 64], and the influence of the atomic motion on the storage and retrieval of pulses in such geometries has been discussed in e.g. [62, 65].

To discuss the influence of the atoms' longitudinal velocities on the cavity field spectrum in an EIT situation in a relatively simple fashion, one can start from the Hamiltonian (II) without switching field and neglecting the variation of the control and probe field Gouy phases and k-vector difference ($k_p \simeq k_c = k$)

$$H_{af} = -\hbar \sum_j g_p \Psi_p(r_j) \cos(kz_j) \hat{a}_p \hat{\sigma}_{31}^{(j)} + \hbar \sum_j g_c \Psi_c(r_j) \cos(kz_j) \hat{a}_c \hat{\sigma}_{32}^{(j)} + \text{h.c.},$$

Introducing $\hat{\sigma}_{31,\pm}^{(j)} = \hat{\sigma}_{31}^{(j)} \exp(\pm ikz_j)$ and $\hat{\sigma}_{32,\pm}^{(j)} = \hat{\sigma}_{32}^{(j)} \exp(\pm ikz_j)$ the optical dipole operators corresponding to the two running wave fields propagating with $\pm k$,

making the same assumptions as in Sec. III I.e. almost all atoms in state $|1\rangle$, constant and strong control field Rabi frequency, one gets equations of motion in an EIT situation which are similar to Eqs. (17,18,19), but now the fields:

$$\dot{a}_p = - (\kappa - i\Delta) a_p + ig_p \sum_j \Psi_p(r_j) (\sigma_{13,\pm}^{(j)} / 2 + \sqrt{2}\kappa_H / \tau_a^{p i n},$$

$$\delta_{13,\pm}^{(j)} = - (\gamma - i\Delta) \sigma_{13,\pm}^{(j)} + i g_p \Psi_p(r_j) a_p (1 + e^{\pm 2ikz_j}) / 2 + i \Omega_c \Psi_c(r_j) \delta_{12}^{(j)} (1 + e^{\pm 2ikz_j}) / 2, \tag{A4}$$

$$\dot{\sigma}_{12} = - (\gamma_0 - i\Delta) \sigma_{12}^{(j)} + i \Omega_c \Psi_c(r_j) (\sigma_{13,\pm}^{(j)} + \sigma_{13,\pm}^{(j)}) / 2. \tag{A5}$$

If the typical timescales for the longitudinal atomic motion (trapping frequencies, thermal motion, ...) are faster than the EIT dynamics timescale, but still slower as compared to the atomic dipole dynamics (i.e. if the typical longitudinal velocity $v$ is such that $\kappa_{EIT} \ll |v| \ll \gamma$, then the terms in $\exp(\pm 2ikz_j)$ can be averaged out in (A1) and one retrieves the "delocalized" situation discussed in this paper or in the experiments of [59]. Physically, this can be explained by the fact that the moving atoms will...
only be in two-photon resonance with the co-propagating parts of the standing waves. As the atoms hence see on average fields with a longitudinal intensity which is half the maximum of the standing wave value, their dipole is reduced which means that the coupling strengths can be effectively rescaled by $1/\sqrt{2}$, yielding the effective Hamiltonian [2].

If we now assume that the atoms are sufficiently cold for their longitudinal positions to be fixed with respect to the longitudinal standing-wave structure of the cavity fields during the EIT interaction, one keeps the longitudinal dependance in the coupling terms to solve the previous equations of motion, which are equivalent to

$$\dot{a}_p = -(\kappa - i\Delta)a_p + ig_p \sum_j \Psi_p(r_j) \cos(kz_j) \sigma_{13}^{(j)} + \sqrt{2\kappa H/\tau a_p^{in}},$$  

(A6)

$$\dot{\sigma}_{13}^{(j)} = - (\gamma - i\Delta)\sigma_{13}^{(j)} + ig_p \Psi_p(r_j) \cos(kz_j)a_p + i\Omega_c \cos(kz_j) \Psi_c(r_j) \sigma_{12}^{(j)},$$  

(A7)

$$\dot{\sigma}_{12}^{(j)} = - (\gamma_0 - i\Delta)\sigma_{12}^{(j)} + i\Omega_c^* \Psi_c(r_j) \cos(kz_j) \sigma_{13}^{(j)}.$$  

(A8)

Solving Eqs. [A6 A7 A8] in steady state yields a susceptibility

$$\chi_{EIT}^{seld} = i \sum_j \frac{g_p^2 \Psi_p(r_j)^2 \cos^2(kz_j)}{\gamma - i\Delta + \frac{\Omega^2 \Psi_c(r_j)^2 \cos^2(kz_j)}{\gamma_0 - i\Delta}}$$  

(A9)

For a large, uniform density ensemble with random longitudinal ion positions along the cavity axis, one gets

$$\chi_{EIT} = \frac{ig_p^2 N}{\gamma - i\Delta} \frac{2 \ln[(1 + \sqrt{1 + 2\Theta})/2]}{\Theta}$$  

(A10)

where $\Theta$ is given by Eq. [21]. The probe field transmission spectrum around two-photon resonance is shown in Fig. 9 for the same parameters as in Fig. 3 in the three situations considered: standard EIT and localized/delocalized all-cavity EIT. The localized situation is seen to give rise to a slightly broader EIT resonance, since the atoms see on average a slightly higher effective control field Rabi frequency, as one would intuitively expects.
