Abstract
A local minimum in the plot of linear reflectance versus angle of incidence, on its own, is insufficient to identify a surface-plasmon-polariton wave (SPPW). Further checks are required in order to confirm the identity of a SPPW. The wavenumber should be compared with that extracted from the dispersion relation for the corresponding canonical boundary-value problem. Also, for prism-coupled configurations such as the Turbadar–Otto configuration which are based on SPPW-excitation via evanescent waves, the angle of incidence should be greater than the critical angle needed for total internal reflection.

Keywords Surface-plasmon polariton wave · Dispersion relation · Evanescent wave

Introduction
Surface-plasmon-polariton waves (SPPWs) are guided by the planar interface of a dielectric material and a metal [1]. These surface waves cannot be excited by direct illumination. Instead, indirect methods of excitation are required, such as prism-coupled methods that utilize evanescent waves to excite SPPWs [2]. An example of such a method is provided by the Turbadar–Otto configuration [3, 4], as schematically illustrated in Fig. 1. This configuration was recently used to investigate SPPWs at the planar interface of a columnar thin film (CTF) made from TiO$_2$ and a thin film of Ag [5].

The authors of Ref. [5] used local minimums in plots of linear reflectance versus angle of incidence (labeled $\theta$ in Fig. 1) to identify SPPWs. However, this means of identifying SPPWs is not sufficiently discriminating: a local minimum is consistent with the excitation of a SPPW but there may well be other explanations for local minimums, such as cavity resonances [6, 7]. It is essential that wavenumbers are compared with those extracted from the dispersion relation for the corresponding canonical boundary-value problem in order to confirm the identity of suspected SPPWs [8].

Using plots of linear reflectance versus angle of incidence in their Fig. 10 (corresponding to CTF vapor deposition angle $\chi_v = 5^\circ$), the authors of Ref. [5] claim to identify two SPPWs: one for the angle of incidence $\theta = 46^\circ$ and the other for the angle of incidence $\theta = 62^\circ$. The local minimum at $\theta = 46^\circ$ is attributed to the Ag-air interface while the local minimum at $\theta = 62^\circ$ is attributed to the CTF-Ag interface. Since the thickness of the Ag film is 40 nm and its skin depth is 23.6 nm (at the chosen free-space wavelength of 633 nm), there should be very little interaction between surface waves at the Ag-air interface and the CTF-Ag interface. On the basis of wavenumbers extracted from the dispersion relation for the corresponding canonical boundary value problems, angles of incidence in the neighborhood of $\theta = 42.92^\circ$ and $\theta = 62.05^\circ$ for the Ag-air interface and the CTF-Ag interface, respectively, are compatible with SPPW excitation. Thus, in the cases of the two claimed SPPWs in Fig. 10 of Ref. [5], the angles of incidence derived from the canonical boundary-value problems are broadly in agreement with those inferred from the plots of linear reflectance.

Let us now turn to plots of linear reflectance versus angle of incidence in Fig. 11 (corresponding to CTF vapor...
deposition angle $\chi = 15^\circ$) of Ref. [5]. The authors claim to identify two SPPWs: one for the angle of incidence $\theta = 31^\circ$ and the other for the angle of incidence $\theta = 70^\circ$. The local minimum in the linear reflectance plot at $\theta = 31^\circ$ is attributed to the Ag-air interface while the local minimum in the linear reflectance plot at $\theta = 70^\circ$ is attributed to the CTF-Ag interface. On the basis of wavenumbers extracted from the dispersion relation for the corresponding canonical boundary-value problems, angles of incidence in the neighborhood of $\theta = 42.92^\circ$ and $\theta = 67.76^\circ$ for the Ag-air interface and the CTF-Ag interface, respectively, are compatible with SPPW excitation. The angle of incidence derived from the canonical boundary-value problem for the Ag-air interface (i.e., $\theta = 67.76^\circ$) is broadly in agreement with that inferred from the plot of linear reflectance in Fig. 11 of Ref. [5] (i.e., $\theta = 70^\circ$). However, the same cannot be said for the Ag-air interface: the angle of incidence derived from the canonical boundary-value problem for the Ag-air interface differs by $12^\circ$ from the angle of incidence for the corresponding local minimum in the plot of linear reflectance. Therefore, the local minimum in the linear reflectance plot at $\theta = 31^\circ$ in Fig. 11 cannot be the signature of a SPPW.

Furthermore, in order to excite a SPPW at the Ag-air interface for the Turbadar–Otto configuration, light entering the air region from the region occupied by the Ag thin film must be in the form of an evanescent wave [1, 2]. Therefore, the angle of incidence in the prism must be greater than the critical angle for total internal reflection at the planar interface of the prism and air. This critical angle is $\sin^{-1}(1/n) = 41.46^\circ$, where $n = 1.5105$ is the refractive index of the prism in Ref. [5]. Consequently, it is not possible to excite a SPPW wave at an angle of incidence $\theta = 31^\circ$, contrary to the claim made in Ref. [5].

In closing, a local minimum in the plot of linear reflectance versus angle of incidence, on its own, is insufficient to identify a SPPW. Additional checks are needed to confirm the identity of a SPPW: The wavenumber should be compared with that extracted from the dispersion relation for the corresponding canonical boundary-value problem. And, for prism-coupled configurations which are based on SPPW-excitation via evanescent waves, the angle of incidence should be greater than the critical angle needed for total internal reflection. Failure to carry out these additional checks has led to a mistakenly identified SPPW in Ref. [5].

Author Contributions Both authors worked on the concept; TGM wrote the first draft; MF helped to finalize.
