Deformed Fermi Surface Theory of Magneto–Acoustic Anomaly
in Modulated Quantum Hall Systems Near $\nu = 1/2$

Abstract

We introduce a new generic model of a deformed Composite Fermion–Fermi Surface (CF–FS) for the Fractional Quantum Hall Effect near $\nu = 1/2$ in the presence of a periodic density modulation. Our model permits us to explain recent surface acoustic wave observations of anisotropic anomalies [1,2] in sound velocity and attenuation – appearance of peaks and anisotropy – which originate from contributions to the conductivity tensor due to regions of the CF–FS which are flattened by the applied modulation. The calculated magnetic field and wave vector dependence of the CF conductivity, velocity shift and attenuation agree with experiments.

PACS numbers 71.10 Pm, 73.40 Hm, 73.20 Dx

The integer and fractional quantum Hall effects (IQHE and FQHE) continue to reveal new and unexpected physics in strongly correlated 2–dimensional electron systems [3]. Recently, particular attention has been given to FQHE systems at and near half filling of the lowest Landau level (LLL). According to the present theory at $\nu = 1/2$ each electron is decorated by two quantum flux tubes, producing a new fermionic quasiparticle, the composite fermion (CF) [4]. At $T = 0$, CFs are distributed inside the Composite Fermion–Fermi Surface (CF–FS), which is assumed to be a circle. When the filling factor of the LLL is changed from $\nu = 1/2$ to $\nu \pm \Delta \nu$, the Chern–Simons based theory makes an important prediction. At $\Delta \nu = 0$, the two flux tubes attached to each electron give rise via the “Chern Simons”
mechanism [3] to an extra (“fictitious”) magnetic field opposite to and exactly canceling, the applied $B$ field. When $\nu = 1/2 \pm \Delta \nu$ ($\Delta \nu \neq 0$) the Chern–Simons field does not cancel the applied field and the CF’s move in a non-zero magnetic field $B_{\text{eff}}$ which is proportional to $\Delta \nu$. In order to test the predictions of this theory it is necessary to measure this field, and the motion of the carriers in it. A sensitive tool for this purpose is surface acoustic wave (SAW) propagation which probes the dynamical response of the quantum Hall system to this $B_{\text{eff}}$ and gives quantitative information about the carriers [5].

Recently [1,2] anomalous behavior was observed for the SAW velocity and attenuation near filling factor $\nu = 1/2$ when a periodic density modulation was applied. Measurements of the velocity shift $\Delta s/s$ and the attenuation $\Gamma$ in the SAW response orthogonal to the modulation direction showed an unexpected effect. The minimum in $\Delta s/s$ at $\nu = 1/2$ which was observed repeatedly in non-modulated systems [5], was converted to a large maximum, when the modulation wave vector, and the magnitude of the external field which produces the modulation, were above some critical values. On further increase of the magnitude of the density modulation, the peak in the velocity shift disappeared and was again replaced by a minimum. For SAW propagation parallel to the direction of density modulation, no such anomaly was found for the response of the electron system.

In this paper we will show that a modulation-induced deformation of the originally circular CF–FS can be at the origin of the observed transport anomalies. We assume that exactly at $\nu = 1/2$ the CF-FS is a circle, with radius $p_F = (4\pi n\hbar^2)^{1/2}$, where $n$ is the electron density. In the presence of the grating modulation the CF–FS circle is “flattened” in the neighborhood of two special points where the curvature vanishes. Such small, locally “flat” regions can under certain conditions, play a disproportionately important role in determining the magneto–conductivity response due to the unusually large density of quasiparticle states there. The response is very sensitive to local changes of FS topology as we show below by introducing a concrete model which permits us to obtain analytical expressions for $\Delta s/s$ and $\Gamma$. Using appropriate parameters we obtain semiquantative agreement with experiment. The model also explains the orthogonality of response and predicts its wave-vector dependence.
We conjecture below that the reason for the reported disappearance of peaks at the highest
modulation is related to additional topological change in the CF–FS.

As a first step, assume the periodic modulation in the y-direction introduces a single
Fourier component of potential $V_g$ into a “nearly–free” particle CF model. The resulting
dispersion relation is:

$$E(p) = \frac{p_x^2}{2m^*} + \frac{p_y^2}{2m^*} + \left(\frac{hg}{2m^*}\right)^2 - \sqrt{\left(\frac{hp^*_y}{2m^*}\right)^2 + V_g^2},$$

with $p_y^* = p_y - hg/2$, $m^*$ is the CF effective mass. The curvature of the 2–D CF–FS can also
be directly calculated as:

$$\kappa = \frac{2v_xv_y \frac{\partial v_x}{\partial p_y} - v_y^2 \frac{\partial v_y}{\partial p_y} - v_x^2 \frac{\partial v_y}{\partial p_x}}{v^3},$$

with $v = \sqrt{v_x^2 + v_y^2}$. The curvature $\kappa$ tends to zero when $p_x \rightarrow \pm p_F\sqrt{V_g/E_F}$. The importance
of this is that near to these points on the CF–FS the CF velocities are nearly parallel to the
y direction. When $ql \gg 1$ ($q$ is the SAW wave vector; $l$ is the CF mean free path) these
parts of the CF–FS make the major contribution to the velocity shift $\Delta s/s$ and attenuation
$\Gamma$ of the SAW propagating in the $x$ direction. Near these zero curvature points we will use
asymptotic expressions for Eq.(1). Determining $(p_x^*, p_y^*)$ by $p_x^* = \eta p_F$, $p_y^* = p_F \left(1 - \frac{1}{\sqrt{2}} \eta^2\right)$,
where $\eta = \sqrt{V_g/E_F}$, $E_F = p_F^2/2m^*$, we can expand the variable $p_y$ in powers of $(p_x - p_x^*)$,
and keep the lowest order terms in the expansion. We obtain:

$$p_y - p_y^* = -\eta(p_x - p_x^*) - \frac{2}{\eta^4} \frac{(p_x - p_x^*)^3}{p_F^2}.$$  

Near $p_x^*$, where $(|p_x - p_x^*| < \eta^2 p_F)$ the first term on the right side of Eq.(3) is small compared
to the second one and can be omitted.

Hence near $p_x^*$ we have:

$$E(p) = \frac{4}{\eta^4 2m^*} \left(\frac{p_x - p_x^*}{p_F}\right)^3 + \frac{p_y^2}{2m^*}.$$  

Using experimental values from [1] we find $V_g \sim 10^{-2} ev$, $n \sim 10^{12} cm^{-2}$. Hence $V_g$ is not
small compared to the Fermi energy and the local flattening of the CF–FS can be quite
significant.
To analyze the contribution to the conductivity from these flattened parts we generalize the expression for $E(p)$ and define our model as:

$$E(p) = \frac{p_0^2}{2m_1} \left| \frac{p_x}{p_0} \right|^\gamma + \frac{p_y^2}{2m_2}, \quad (5)$$

where $p_0$ is a constant with the dimension of momentum, the $m_i$ are effective masses, and $\gamma$ is a dimensionless parameter which will determine the shape of the CF–FS. We shall take $\gamma > 1$ to avoid singularities in the CF velocity. When $\gamma > 2$ the 2-D CF–FS looks like an ellipse flattened near the vertices $(0, \pm p_0)$. Near these points the curvature is:

$$\kappa = -\frac{\gamma(\gamma - 1)}{2p_0 \sqrt{m_2/m_1}} \left| \frac{p_x}{p_0} \right|^{-2}, \quad (6)$$

and, $\kappa \to 0$ at $p_x \to 0$. The CF–FS will be the flatter at $(0, \pm p_0)$, the larger is the parameter $\gamma$. We can now calculate the desired responses to the SAW, using Eq.(5).

In a GaAs heterostructure with a 2-D electron gas subject to a travelling SAW, piezoelectric coupling produces a longitudinal electric field which interacts with the electron gas. Taking the SAW wave vector as $(q, 0, 0)$ we obtain that the resulting velocity shift $\Delta s/s$ and SAW attenuation rate $\Gamma$ are given by the following expressions [6]

$$\Delta s/s = \frac{\alpha^2}{2} \Re \left(1 + i\sigma_{xx}/\sigma_m\right)^{-1}, \quad (7)$$

$$\Gamma = -q(\alpha^2)/2\Im \left(1 + i\sigma_{xx}/\sigma_m\right)^{-1}. \quad (8)$$

In these equations, $\omega = sq$ is the SAW frequency, $\alpha$ is the piezoelectric coupling constant, $\sigma_m = \epsilon s/(2\pi)$ with $\epsilon$ an effective dielectric constant of the medium, $\sigma_{xx}$ is the $xx$ component of the electronic conductivity tensor; real and imaginary parts are indicated. In order to proceed we now need to establish some preliminary results. We use the semi–classical CF theory [4] in which the CF quasiparticles have charge $e$, and finite mass $m^*$. However, as described below, a particular variant of the solution of the Boltzmann equation was needed for the present work. In semiclassical CF theory the electron resistivity tensor $\rho$ at finite $(q, \omega)$ is the sum of a CF term and a term originating in the magnetic field of the Chern-Simons (CS) vector potential. The CS part has only off–diagonal elements,
(\rho^{CS})_{xy} = -(\rho^{CS})_{yx} = 4\pi \hbar/e^2. \quad (9)

In a strong magnetic field we have \( \rho_{xy} \gg \rho_{xx}, \rho_{yy} \), and hence we can use the approximation:

\[ \sigma_{xx}(q) = e^4 / [(4\pi \hbar)^2 \tilde{\sigma}_{yy}(q)], \quad (10) \]

where \( \tilde{\sigma} = (\rho^{CF})^{-1} \) is the CF conductivity.

We shall calculate the CF conductivity tensor at \( \nu \) close to \( 1/2 \), using the resulting non-zero effective magnetic field which contains a spatially nonuniform contribution \( \Delta B \exp(igy) \) associated with the electron density modulation \( \Delta n(y) \) as:\n
\( \Delta B(y) = -(4\pi \hbar c/e)\Delta n(y) \). Consequently, we assume we can replace the initial system of CFs with a system of quasiparticles containing \( n+ <\Delta n> \) negatively charged quasielectrons (fermions) and \( <\Delta n> \) positively charged quasiholes (fermions) per unit area. Here \( <\Delta n> \) is equal to the root mean-square value of \( <\Delta n(r)> \), and corresponds to the additional average fictitious magnetic field \( <\Delta B> \). We assume that we can consider the response of this two component system in the uniform effective magnetic field \( B^*_{eff} = B_{eff} + <\Delta B> \), instead of the response of the initial one-component CF system in the nonuniform effective magnetic field.

To evaluate the quasielectron contribution to the CF conductivity \( \tilde{\sigma}^e_{\alpha\beta}(q) \) so that we can pass smoothly to the \( B_{eff} \to 0 \) limit for a flattened CF–FS, we begin with the expression obtained from solution of the linearized Boltzmann equation in the presence of the magnetic field, assuming a relaxation time \( \tau \). This is:

\[
\tilde{\sigma}^e_{\alpha\beta}(\nu) = \frac{e^2 m_c}{(2\pi \hbar)^2} \frac{1}{\Omega} \int_0^{2\pi} d\psi \left\{ \exp \left[ -\frac{iq}{\Omega} \int_0^\psi V_x(\psi'')d\psi'' \right] V_\alpha(\psi) \times \right.
\]

\[
\times \int_{-\infty}^\psi \exp \left[ \frac{iq}{\Omega} \int_0^{\psi'} V_x(\psi')d\psi' + \frac{1}{\Omega\tau}(\psi' - \psi) \right] V_\beta(\psi')d\psi' \right\}. \quad (11)
\]

Here \( V_{\alpha,\beta} \) are the quasielectron velocity components \( (\alpha, \beta = x, y) \); \( \Omega = |e|B^*_{eff}/m_c \) is their cyclotron frequency; \( \psi \) is the angular coordinate on the quasielectron cyclotron orbit, \( (\psi = \Omega \theta; \theta \) is the time of the quasielectron motion along the cyclotron orbit). We have taken \( \omega \tau \ll 1 \). We proceed [7] as follows. Express the velocity components \( V_\beta(\psi') \) as Fourier series:
Equation (12)

\[ V_\beta(\psi') = \sum_k V_{k\beta} \exp(ik\psi'). \]

Introducing a new variable \( \eta \):

\[ \eta \equiv \left( \frac{1}{\tau} + ik \Omega + iq V_x(\psi) \right) \bar{\theta} + i q \int_0^\theta [V_x(\psi + \Omega \theta') - V_x(\psi)] d\theta' \]

and substituting (11) and (12) into (10) we obtain:

\[ \tilde{\sigma}_e^{\alpha\beta}(\nu) = \frac{e^2 m_c \tau}{(2\pi \hbar)^2} \sum_k V_{k\beta} \int_0^0 d\eta \int_{-\infty}^{2\pi} \frac{V_\alpha(\psi) \exp(ik\psi) d\psi}{1 + ik \Omega \tau + i q V_x(\psi + \theta(\eta) \Omega) \tau}. \]

To proceed we can transform the integral over \( \psi \) in (14) to an integral over the CF–FS. Reexpressing the element of integration as \( m_c d\psi = d\lambda/|v| \) (\( d\lambda \) is the element of length along the Fermi Arc) and \( m_c \) will be replaced by a suitable combination of \( m_1, m_2 \) of our model (5); e.g., for an ellipse \( m_c = \sqrt{m_1 m_2} \). We can now parameterize the dispersion equation of our model (5) as follows:

\[ p_x = \pm p_0 |\cos t|^{2/\gamma}; \quad p_y = p_0 \sqrt{m_2/m_1} \sin t, \]

where \( 0 \leq t \leq 2\pi \), and the + and – signs are chosen corresponding to normal domains of positive and negative values of the cosine. Where \( ql \gg 1 \), the leading term in the resulting formula originates from parts of the CF–FS where \( v_x \approx 0 \). Expanding it in powers of \((ql)^{-1}\) and keeping the main term in the expansion we obtain:

\[ \tilde{\sigma}_y^{\nu}(\nu) = \frac{b}{24\pi \hbar^2} \frac{1}{ql\mu} \left( S_{+\mu}(\Omega \tau) + S_{-\mu}(\Omega \tau) \right) \]

where: \( S_{\pm\mu}(\Omega \tau) = \int_{-\infty}^0 e^{\eta}(1 \mp i \Omega \tau(1 \pm \eta \delta_0))^{\mu-1} d\eta \) and \( \delta_0 \) is a small dimensionless constant of the order of \( \omega \tau \). Here for convenience we introduced \( \mu = 1/(\gamma - 1) \) which is a dimensionless parameter \((0 \neq \mu \leq 1)\), with \( \mu = 1 \), or \( \gamma = 2 \) corresponding to the case that the CF–FS is an ellipse. In these variables, the CF mean-free-path \( \ell \) is equal to:

\[ \ell = \frac{\mu + 1}{2\mu} \frac{p_0 \tau}{m_1}. \]

Passing to the limit \( B_{eff} = 0 \) we have:
\[
\tilde{\sigma}_{yy}^e (\nu = \frac{1}{2}) = \frac{be^2p_0}{4\pi\hbar^2} \frac{\ell}{(q\ell)\mu}.
\] (18)

In this equation \( b = 4\mu^2/(\mu + 1)\sqrt{m_1/m_2}[\sin(\pi\mu/2)]^{-1} \). This expression eqn.(18) predicts that measuring the \( q \)-dependence of the conductivity exactly at \( B_{eff}^* = 0 \) (\( \nu = 1/2 \)) can give the deformation parameter \( \mu \). When the CF–FS is an undeformed circle (\( m_1 = m_2 = m^* \)) then \( b = 2 \) and the result is identical to the corresponding result obtained in [4]. It is worth emphasizing that under the condition that the flattening of the CF-FS is strong, with \( \gamma \gg 1 \), the quantity \( \mu \approx 0 \) and the CF conductivity will be enhanced compared to the circular case, and it will be effectively independent of \( q \) (See eqn.(16)). Independence of \( q \) has been found experimentally [1]. For small \( \Omega\tau, (\Omega\tau\omega\tau < 1) \) one can expand the functions \( S_{\pm\mu}(\Omega\tau) \) (\( \mu \neq 1 \)) in powers of \( \delta_0\Omega\tau \):

\[
S_{\pm\mu}(\Omega\tau) = (1 \mp \Omega\tau)^{\mu-1} \left[ 1 + \sum_{r=1}^{\infty} \frac{(1 - \mu)(2 - \mu)...(r - \mu)}{(1 \mp i\Omega\tau)^r} (i\delta_0\Omega\tau)^r \right].
\] (19)

Keeping the terms larger than \( (\Omega\tau)^3 \) one has:

\[
\tilde{\sigma}^{(e)}_{yy} = \tilde{\sigma}_{yy}^e \left( \nu = \frac{1}{2} \right) [1 - a^2(\Omega\tau)^2 + i\xi\Omega\tau].
\] (20)

Here \( a^2 = ((1 - \mu)(2 - \mu)/2)(1 + 2\delta_0^2) \) and \( \xi = (1 - \mu)\delta_0 \) are positive constants. For sufficiently small values of the parameter \( \mu \) (significant flattening of the effective parts of the CF–FS) the constant \( a^2 \) is of the order of unity and the constant \( \xi \) is small compared to unity, because of the small factor \( \delta_0 \).

In the experiments [1,2] the quasihole density \(<\Delta n>\) and the corresponding Fermi momentum is small compared to these for the quasielectrons. Therefore the quasihole contribution to the CF conductivity can be neglected. Substituting the result (16) into (10), we can obtain the expression for the electron conductivity component \( \sigma_{xx} \). The using (7),(8) we have:

\[
\frac{\Delta s}{s} = a^2 \frac{1}{2} \frac{1 + \xi\Omega\tau}{1 + \tilde{\sigma}^2} \left( 1 - \frac{2\xi\Omega\tau}{1 + \tilde{\sigma}^2} \frac{\tilde{\sigma}^2}{1 + \tilde{\sigma}^2} (2a^2 - \xi^2)(\Omega\tau)^2 \right);
\] (21)

\[
\Gamma = q^2 a^2 \frac{1 + \tilde{\sigma}^2}{2} \left( 1 - \frac{2\xi\Omega\tau}{1 + \tilde{\sigma}^2} \frac{\tilde{\sigma}^2}{1 + \tilde{\sigma}^2} (\Omega\tau)^2 \right).
\] (22)
Here $\sigma = \sigma_{xx}(\nu = 1/2)/\sigma_m$. Expression (21) and (22) are the new results of our theory. They predict peaks both in the SAW attenuation and velocity shift at $\nu = 1/2$. The peaks arise due to distortion of the CF–FS in the presence of the density modulation. When the CF–FS flattening is strong ($\mu \ll 1$) the magnitude of the peak of the velocity shift is practically independent of the SAW wave vector $q$. Also these anomalies are not sensitive to any relation between $q$ and the density modulation wave vector $g$. As was observed repeatedly [1,2] the peaks appear when the magnitude of the modulating potential and its wave vector are sufficiently large. These quantities $V_g$ and $g$ determine the character and amount of distortion of the CF–FS.

Our model allows us to obtain the dependence of the conductivity on filling factor $\nu$ for the undistorted (circle) CF–FS, when $\mu = 1$. In that case, the main term in the expansion of the CF conductivity in inverse powers of $ql$ is independent of the magnetic field. When we take into account the next term of the expansion we arrive at the following expression after a lengthy, but straightforward calculation [10]:

$$\tilde{\sigma}_{yy}(\nu) = \frac{2e^2 p^2 \tau}{(2\pi \hbar)^2 m^*} \int_{-\infty}^{0} e^{\eta} \left( \frac{\pi}{ql} + 2\Omega \frac{\ln(ql)}{(ql)^2} + \Omega \tau f(\eta)O(ql)^{-1} \right) d\eta$$

(23)

where $O$ means “order of “.

Now, noting that the first two terms are independent of $\eta$, and retaining only them in doing the integral, we obtain the CF conductivity tensor component:

$$\tilde{\sigma}_{yy}(\nu) = \tilde{\sigma}_{yy}\left(\nu = \frac{1}{2}\right) \left[ 1 + \Omega \tau \frac{2\ln(ql)}{\pi ql} \right].$$

(24)

Expression (23) describes the CF conductivity increasing as $B_{eff}$ increases. This corresponds to the minimum in the SAW velocity shift at $\mu = 1/2$. This minimum was observed repeatedly in non-modulated FQHE systems [5].

We now suggest an explanation for the observed disappearance of the SAW peak in $\Delta s/s$ when the magnitude of density modulation was at highest measured values. In metals it is known [8,9] that external factors, as well as changes in electron density can cause changes in FS topology. Such changes are sensitively reflected in the response functions. We suggest this
can occur in the CF case. A topological change of the CF–FS connectivity can be caused by increased magnitude of modulating field and correspondingly increased quasiparticle density \( n + \langle \Delta n \rangle \). Changing the CF–FS connectivity can lead to the disappearance of the flattening of the effective parts of the CF–FS. In this case the anomalous maximum in the magnetic field dependence of \( \Delta s/s \) will be replaced by minimum. Thus assuming the relevance of the electron topological transition, we can explain the disappearance of the peak in the SAW velocity shift under increase of the modulation strength. Additional experimental consequences of our model and more details of the theory will be presented elsewhere [10].

Recently, several other theoretical papers have discussed [11,12] the experiments on density modulated systems near \( \nu = 1/2 \), although our explicit deformed CF–FS model is new, to our knowledge. A point of contact between our work and that of [11] may be their assertion of anisotropic resistivity due to the spatially averaged current and electric field in the presence of periodically modulated quasiparticle density [see eqn (2) of ref 11]. This assertion seems implicitly to correspond to our deformed CF–FS; the two approaches would then be equivalent when \( \Delta n \ll n \). However, in [11,12] it was assumed that the wavelength of the density modulation is small compared to the SAW wavelength \( (g \gg q) \), and also that the interaction energy of the CF with the modulating field is small compared to the Fermi energy. According to our estimate as presented above, these assumptions do not correspond to the reported experiments.

We again remark that our work is based on the charged CF picture for FQHE, for example as derived at \( \nu = 1/2 \) in ref. [4] from a Chern–Simons approach. An alternate picture for the FQHE also derived from a Chern–Simons approach, gives the quasiparticles at \( \nu = 1/2 \) as neutral dipolar objects, with the Hall current being carried by a set of collective magneto–plasmon oscillators. To our knowledge, a magneto–transport theory based on this second picture does not exist at present, so we are not able to compare our results with any derived from that picture.

We thank Dr.R.L.Willett for discussions, Mr. Meng Lu and Dr.Gregory Zimovsky for help with the manuscript. This work was supported in part by a grant from the National
Research Council COBASE Program.
