Case report

A B S T R A C T

INTRODUCTION: Oral squamous papilloma is a benign tumor, but its potential for malignant transformation has yet to be studied. The authors report an unusual case presentation of an oral squamous cell carcinoma (SCC) arising from a squamous cell papilloma (SCP).

CASE PRESENTATION: A 61 years old immunocompromised female patient complained of an asymptomatic white mass on the buccal mucosa. The diagnosis of squamous cell papilloma (SCP) was made, and the benign nature of the lesion was confirmed by two biopsies. The lesion suddenly increased in size, and the third biopsy revealed a malignant squamous cell carcinoma (SCC) grade II. At this stage, radical surgical intervention was the treatment of choice, and reconstruction with a combination of the pectoralis major and deltopectoral flaps was performed.

DISCUSSION: Clinical and histopathological diagnosis of oral squamous papilloma is challenging. Reconstruction of composite head and neck defects is another challenge, especially in elderly and immunocompromised patients. The whole process of diagnosis and progress of the presented case might provide useful knowledge regarding the nature of the lesion and its future management.

CONCLUSION: The authors emphasize the need for establishing a clear understanding of potentially malignant oral lesions. Close observation, multiple biopsies, early detection, precise diagnosis, and a multidisciplinary team approach are all of paramount importance.

1. Introduction

The worldwide updated cancer prevalence reported an increase in the incidence of oral cancer [1]. Despite that, it was regarded as the sixth most common cancer worldwide [2]. Oral squamous cell carcinoma accounts for 90% of the histologic type of oral cancer [3] and may or may not be preceded by oral potentially malignant disorders. The association of viruses and cancer was well documented. More than 20% of cancer prevalence worldwide could be related to infectious agents, including viruses, bacteria, and parasites. Over 15% of these cases are associated with viruses [4]. Human papillomavirus (HPV) is an epitheliotropic oncogenic DNA virus rarely found in oral mucosa, probably due to saliva clearance [5]. Nevertheless, more than 200 genotypes were detected in the oral mucosa [6]. HPV infection of the oral mucosa may result in benign or malignant disease. The role of HPV as an independent risk factor in oral carcinogenesis was well recognized in the literature [3]. HPV positivity claimed to override traditional prognostic indicators such as tumor grade and histological subtype [7]. However, other studies reported a non-significant association between HPV and oral cancer, suggesting its presence to be merely an incidental finding [8].

According to the classification of the World Health Organization (WHO), oral squamous cell papilloma is a benign hyperplastic exophytic localized proliferation with a verrucous or cauliflower-like morphology, which its base may be sessile or pedunculated [9]. It was reported to have two types: isolated-solitary in adults and multiple-recurring in children. The color of the lesion varies depending on the level of keratinization and vascularization [9]. Oral squamous papilloma is regarded as an innocuous lesion that is neither transmissible nor threatening [10]. The virulence and infectivity of oral papillomas are very low, unlike other HPV-induced lesions [11]. The site and size of oral papilloma can be used as risk factors for malignant transformation [12]. Although any intraoral site may be affected, the palate, tongue, lips, and gingiva are the most common. However, those present on the gingiva are associated with a higher risk of malignant transformation [13]. Also, if the
size of the oral papilloma is larger than 10 mm, the risk increases [14].

Although untreated lesions of oral squamous papilloma do not usually change over time, several treatment modalities can be implemented. Conventional surgical excision without safety margin, cauterization or cryosurgery, electrocautery, intralesional injection of interferon, and the application of salicylic acid [15]. Laser ablation can also be used but with caution because viral particles are reported to be found in laser plumes after laser ablation [16]. The possibility of prophylactic HPV vaccination is certainly hope but may not be useful for treating existing disease. It is a necessity to develop effective prevention and treatment methods. The presented case report is in line with SCARE guidelines [17].

2. Case history

A 61 years old female patient, with a chief complaint of an intraoral white lesion covering the mucosa of the right cheek that appeared 2 years ago (Fig. 1). The patient was a non-smoker and non-drinker and suffered from end-stage renal disease (ESRD). The undertaken biopsy from the right buccal mucosa and histopathological examination revealed an oral squamous papilloma (Fig. 2). A year later, a second biopsy performed, and the pathological diagnosis of an oral squamous papilloma persisted.

The patient presented 6 months later, complaining of the enlargement and change in the consistency of the lesion causing discomfort and dysfunction. Clinical examination revealed that the lesion extended to involve the floor of the mouth (Fig. 3) and the extraoral skin of the right cheek (Fig. 4). Bilateral suspicious lymph nodes were also noted. MRI and CT scan with contrast revealed a well-defined soft tissue mass measuring 6.2 × 2.5 × 3.5 cm along its maximum dimensions. The lesion was opposite the mandibular body (likely deep to buccinators muscle) with no evidence of bone erosion. It displayed a hypointense signal in T1WIs and hyperintense signal in STIR images with faint homogenous post-contrast enhancement. Multiple submental and bilateral submandibular lymph nodes were displaying no intrinsic calcifications or areas of breaking down. The largest of which was at the right submandibular group measuring 17 × 10 mm.

![Fig. 4. Showing intraoral and extraoral extension of the lesion.](image4)
The multidisciplinary team included surgical oncologists, oral and maxillofacial surgeons, surgical pathologists, and maxillofacial prosthetists. The treatment plan was dictated by the severity of the condition. Neck dissection, hemimandibulectomy, and the placement of a reconstruction plate to bridge the mandibular defect were performed. The combination of Pectoralis major flap for intraoral reconstruction and deltopectoral flap for extraoral coverage were used. The two flaps raised at the same time without compromising the vascularity of each other as described by McGregor, I.A. [18]. The postoperative pathological diagnosis was squamous cell carcinoma (SCC) grade II (Figs. 5, 6). The histopathological analysis of the dissected lymph nodes showed no metastatic involvement. The duration of postoperative follow-up was short since the patient died of complications of acute renal failure 1 month postoperative.

3. Discussion

Some authors define oral cancer as the group of neoplasms affecting any region of the oral cavity, oropharyngeal regions, and salivary glands, which accounts for the most majority of head and neck cancer [19]. While others define it as the neoplasm involving the oral cavity and begin at the lips and ends at the anterior pil-
