Abstract

Introduction: Subarachnoidal hemorrhage (SAH) occurring after aneurismal rupture produces an inflammatory response in the cerebral circulation. Tumor necrosis factor (TNF-α) is a major cytokine in this process. Adhesion molecules provide information on inflammatory reactions taking place in the walls of blood vessels. Clinical evidence suggests a role of soluble intercellular adhesion molecule (sICAM)-1 in early hemorrhagic events. This study aimed to evaluate the implementation of early TNF-α and sICAM-1 serum measurement for the prognosis of patient outcome after intracranial aneurismal rupture.

Materials and Methods: The study consisted of 27 patients with a diagnosis of intracranial aneurysm. SAH was evaluated on admission according to the Fisher scale, patients’ consciousness with the Glasgow Coma Scale, clinical grading with the Hunt and Hess scale, and clinical outcome with the Glasgow Outcome Scale (GOS). Blood samples were drawn within 72 h after arrival at the emergency room. Serum concentrations of TNF-α and sICAM-1 were assayed with the ELISA method.

Results: The initial serum TNF-α concentration in the aneurismal patients was low and did not correlate with radiological and clinical scores. The serum sICAM-1 level positively correlated with the severity of bleeding assessed by the Fisher scale and negatively with the patient’s scoring in the GOS.

Conclusions: This study demonstrated the absence of a systemic TNF-α-mediated inflammatory response at the onset of subarachnoid hemorrhage. Early measurement of serum sICAM-1 levels offers a potential prognostic value in the assessment of patients’ outcome after brain aneurismal rupture.

Key words: TNF-α, sICAM-1, brain, aneurismal rupture.

Abbreviations: ELISA - enzyme-linked immunosorbent assay, SAH - subarachnoidal hemorrhage, sICAM-1 – soluble intercellular adhesion molecule-1, TNF-α – tumor necrosis factor α, GCS – Glasgow Coma Scale, GOS – Glasgow Outcome Scale.

INTRODUCTION

Intracranial aneurysms are often defined as weakened, abnormally dilated walls of the major arteries (Selman et al. 2000). The aneurysm is usually asymptomatic for a long time until rupture (Raps et al. 1993). A consequence of an aneurysmal wall burst is blood leakage into the cerebral structures, which may lead to irreversible brain damage and death (Inagawa et al. 1995). The incidence of intracranial aneurysm in the general population is estimated to be about 4–6% (Rinkel et al. 1998). Inherited syndromes, traumatic or infectious diseases, and behavioral influences have been specified among the risk factors (De Brackeleer et al. 1996; Wardlaw and White 2000). Subjects of female gender, aged over 50, hypertensive, hypercholesterolemic, or with a current smoking history are prone to develop brain aneurysms (Wardlaw and White 2000). Coffee consumption may increase the incidence of aneurismal subarachnoidal hemorrhage (SAH) (Isaksen et al. 2002). The potential influence of alcohol consumption is under investigation (Wardlaw and White 2000).

SAH occurring after aneurismal rupture produces an inflammatory response in the cerebral circulation mediated by proinflammatory cytokines (Fassbender et
al. 2001; Takizawa et al. 2001). Tumor necrosis factor (TNF-\(\alpha\)) is one of the key immune activators of leukocytes counteracting the underlying pathological condition. Stimulated by cytokines, the inflammatory process may promote the development of cerebral vasospasm and ischemia, which negatively affect a patient’s outcome after SAH (Dumont et al. 2003; Hirashima et al. 1997).

Adhesion molecules provide information on inflammatory reactions which occur in the walls of blood vessels (Witkowska 2005). Soluble intercellular adhesion molecule (sICAM)-1 is a circulating form of ICAM-1, a molecule that is crucial for leukocyte adhesion to endothelial cells in the process of leukocyte migration through the vessel’s wall. Clinical evidence suggests that sICAM-1 may be engaged in the process of cerebral vasospasm (Mocco et al. 2002), and late elevated levels of serum sICAM-1 were predictors of poor outcome after aneurismal SAH (Mack et al. 2002).

Inflammatory cytokines and adhesion molecules may contribute to complications after intracranial hemorrhage, with dramatic consequences for the patient’s survival (Dhar and Diringer 2008; Dumont et al. 2003). Hence this study aimed to evaluate the relationships between early TNF-\(\alpha\) and sICAM-1 serum levels and prognosis after aneurismal rupture.

**MATERIALS AND METHODS**

The protocol of the study was approved by the local bioethics committee. The participants were 27 patients with a diagnosis of ruptured intracranial aneurysm admitted to the Department of Neurosurgery for lifesaving surgery. Their detailed data are shown in Table 1. Seventeen healthy subjects of both genders, aged between 38–71 years (mean age: 55 years), took part in the examinations as the control group.

SAH was evaluated on admission using computed tomography and graded according to the Fisher scale (Fisher et al. 1980). The patients’ consciousness was assessed upon admission by computed tomography are shown in Table 2. On admission, 67% of the subjects showed signs of cerebral bleeding of different degrees (grades 2–4 on the Fisher scale). The patients’ grading according to the GCS was between 11 and 15. Seventy-four percent of the patients presented with grades 0–1 on the Hunt and Hess scale. The patients’ rating on the GOS was between 3 and 5 for 81% of the subjects. The death rate was about 19% (5 patients died during the hospitalization).

Comparisons of the parameters tested in the patients with intracranial aneurysms vs. controls are shown in Table 3. No differences in the mean serum TNF-\(\alpha\) and sICAM-1 concentrations of the aneurismal subjects and controls were observed.

The serum TNF-\(\alpha\) concentration did not correlate with the radiological and clinical scores (Table 4). The concentration of sICAM-1 positively correlated with the Fisher grade (r=0.439) and negatively with the GOS (r=-0.423).

Serum sICAM-1 concentration in relation to the Fisher and the GOS grading is shown in Fig. 1. A gradually increasing sICAM-1 concentration in relation to the Fisher score was observed. The patients who scored 4 had significantly elevated serum sICAM-1 levels compared with the controls. The sICAM-1 concentration

**RESULTS**

The patients’ clinical presentation and radiological assessment by computed tomography are shown in Table 2. On admission, 67% of the subjects showed signs of cerebral bleeding of different degrees (grades 2–4 on the Fisher scale). The patients’ grading according to the GCS was between 11 and 15. Seventy-four percent of the patients presented with grades 0–1 on the Hunt and Hess scale. The patients’ rating on the GOS was between 3 and 5 for 81% of the subjects. The death rate was about 19% (5 patients died during the hospitalization).
negatively correlated with the scores obtained from the GOS. The patients who were graded 4 and 5 had low serum sICAM-1 levels, comparable to those of the controls. The patients who scored 1 or 3 had significantly higher sICAM-1 levels than the controls and the patients who scored 5.

**DISCUSSION**

SAH is a life-threatening consequence of an intracranial aneurysm’s rupture, which may be lethal for nearly 50% of patients (Inagawa et al. 1995). Disruption of a cerebral artery causes blood extravasations which may induce cytokine-stimulated immune reactions contributing to the development of cerebral vasospasm and ischemia. Systemic inflammation develops in a few days after hemorrhage. TNF-α is a major cytokine in the initiation of inflammatory reactions. Significantly increased TNF-α levels in the cerebrospinal fluid were observed 4–10 days after SAH (Mathiesen et al. 1997). In the present study, early TNF-α levels were studied. Blood samples were taken from the patients within 72 h after admittance to the hospital. The data analysis showed similar TNF-α levels in the aneurysmal patients and controls. No correlation of TNF-α levels with the radiological and clinical scores was observed. In many pathological conditions, TNF-α stimulates an inflammatory response. The low TNF-α levels observed in the sera of the aneurismal patients within three days of hospitalization suggest the absence of systemic inflammation during the early hemorrhagic events.

Leukocyte penetration through the blood-brain barrier into the subarachnoidal space is facilitated by adhesion molecules on the surface of endothelial cells. sICAM-1, a released form of the membrane molecule, is present in cerebrospinal fluid and blood. Several studies demonstrated an increase in serum sICAM-1 after aneurysmal rupture (Frijns et al. 2006; Mack et al. 2002; Nissen et al. 2001). Interesting observations concerning patients’ outcome after SAH were made by Mack et al. (Mack et al. 2002). They observed that sICAM-1 levels were elevated in early hemorrhagic events and that late high sICAM-1 levels were predictors of critical outcome. Several other studies did not find significant associations between patient outcome and serum sICAM-1 levels measured at the onset of SAH (Frijns et al. 2006; Nissen et al. 2001). Contrary to these findings, the

![Fig. 1. Serum sICAM-1 concentration (means±SD) according to the Fisher scale and the Glasgow Outcome Scale (GOS).](image-url)
results obtained in the present study show associations of early serum sICAM-1 levels with patient outcome after SAH. The serum sICAM-1 concentration correlated with the scores obtained in the Fisher and the GOS. The former results demonstrate a clear connection between serum sICAM-1 concentration and the intensity of bleeding. At the same time, high sICAM-1 had a predictive value of poor outcome. The patients who were graded low in the GOS (1 or 3 points) had significantly elevated sICAM-1 titers compared with the healthy controls and the patients with the best scores.

This study demonstrates the absence of a systemic inflammatory TNF-α-mediated response at the onset of subarachnoid hemorrhage. Early measurement of serum sICAM-1 levels offers a prognostic value in the assessment of patient outcome after brain aneurismal rupture.
