A high proportion of triatomine insects, vectors for *Trypanosoma cruzi* trypanosomes, were collected in Arizona and California and examined using a novel assay that fed on humans. Other triatomine insects were positive for *T. cruzi* parasite infection, which indicates that the potential exists for vector transmission of Chagas disease in the United States.

Chagas disease is a vector-borne disease caused by *Trypanosoma cruzi* trypanosomes. Although these parasites are rarely transmitted by insects in the United States, there is concern that vector transmission may increase (1). Chagas disease, endemic to most of Latin America, can be transmitted to mammals by >130 species of blood-feeding insect vectors (subfamily Triatominae). In the United States, the most common result of a triatomine bite is allergic reaction, including anaphylaxis, elicited in sensitized persons (2). Despite only 7 cases of vector transmission to humans reported in the United States (3,4), *T. cruzi* trypanosomes are present in >20 wildlife species. In Latin America, 8–10 million persons are infected by these parasites (5), and an estimated 300,000 of the ≈13 million persons from disease-endemic areas now living in the United States carry the parasite (6). Although vector transmission of *T. cruzi* trypanosomes is a minimal risk, 9 of the 11 triatomine species in the United States are potential vectors (1,7), and parasite transmission could increase because of climate change (1).

One critical aspect of transmission is parasite reservoirs; hence, the epidemiologic importance of identifying animal sources of the vectors’ blood meals, the likelihood of these vectors also feeding on humans, and their incidence of *T. cruzi* infection. Blood meals consumed by insect vectors have been detected by using several molecular techniques (8), but assays are challenging because of degradation of the blood in the vector’s gut, PCR inhibition, the often small size of a blood meal, and the difficulty of distinguishing multiple blood meals. We analyzed *T. cruzi* vectors collected in California and Arizona by using a novel technique—cloning following PCR amplification using universal vertebrate primers—to determine the source of blood meals and indicate the likelihood of parasite transmission to humans.

### The Study

Insects were collected by using light traps at Redington Road, Tucson, Arizona, and Escondido, California, in 2007, and within the Arizona-Sonora Desert Museum, Tucson, in 2009 (Table 1). We examined blood meals (9) and *T. cruzi* parasite infection (10) of 13 insects from 2 species of kissing bugs, *Triatoma rubida* and *T. protracta*. A mouse-fed *T. recuva* bug served as a control (11). Using universal vertebrate primers for cytB and 12S (12,13), we identified as many blood meals as possible (Table 1). We cloned and sequenced the PCR products to isolate multiple blood meals within a single insect (Table 2). Blood meal sources were inferred by using BLAST (http://blast.ncbi.nlm.nih.gov/Blast.cgi). Pearson χ² tests compared the likelihood of feeding on humans between vector species and compared the cytB and 12S assays for differences in the number of blood meal taxa and blood meal haplotypes (i.e., unique DNA sequences) per insect (JMP Ver9; SAS, Cary, NC, USA).

Five of the 13 bugs (38%) had positive test results for human blood (Table 1); *T. rubida* bugs were significantly more likely than *T. protracta* bugs to have fed on humans (χ² 9.24; p<0.01). *T. rubida* bugs had also fed on dogs and *T. protracta* bugs on woodrats (*Neotoma* spp.), chickens, dogs, and pigs. *T. cruzi* infection was found in 5/9 *T. protracta* and 0/4 *T. rubidia* bugs. No insect that had fed on humans was infected with *T. cruzi* trypanosomes.

The cytB and 12S assays differed in the specificity of primers for vertebrate DNA and number of blood meals per insect (Figure). More than 70% of DNA cloned in the cytB assay was from the insect (64/87 clones); ≈10% of clones did not produce interpretable sequences. In contrast, the 12S assay did not clone insect DNA, and all sequences were interpretable. The average number of blood meals per insect was not statistically different (cytB 0.56 taxa/insect, 12S 1.75 taxa/insect; χ² 8.31; p<0.10); however, the average number of haplotypes/insect was significantly higher for 12S (cytB 0.78, 12S 2.75; χ² 9.09; p<0.02).
The cytB assay detected more haplotypes from each blood meal taxon, indicating the bugs fed on unique individuals; 4 human and 2 woodrat sequences were all different from each other. In contrast, for 12S, 17/18 dog sequences were identical, as were 2/3 human and 3/4 pig sequences.

The mouse-fed control was the only insect for which no vector DNA was cloned in the cytB assay. All 8 clones from the control were mouse; 7 were identical. Although unexpected, heteroplasmic mitochondrial DNA has been reported for inbred mice (14).

Conclusions
We found that 38% bugs of 2 species of T. cruzi vectors endemic to the United States, T. rubida and T. protracta, fed on humans. Infection with the Chagas parasite, T. cruzi, was high (55% for T. protracta bugs), but no insect was positive for human blood meals and the parasite. Both vectors are common in the foothills of Tucson, Arizona (2); although the T. rubida bugs in this study were uninfected, another study found that 67% of adult bugs collected around Tucson were infected with T. cruzi parasites (15).

The Arizona-Sonora Desert Museum in Tucson exhibits desert animals. All 4 insects collected from near the museum had fed on canids (dog/coyote/wolf; Canis spp.); 1 had fed on pigs and 2 on humans. Although canid samples are not distinguishable by 12S, there are no dogs at the museum, so the insects probably fed on coyotes or wolves. Although javelina (Tayassu tajacu), a species similar to pigs, are at the museum, sequences were 99% identical to pig (Sus scrofa) and only a 90% match with javelina. The source of the human blood meals is not

Table 1. Blood meal sources of Trypanosoma cruzi insect vectors collected in Arizona and California, USA, 2007 and 2009, as determined by using cytB and 12S rDNA assays, and haplotypes identified.†

| Assay and reference | T. cruzi Location† | Clones | Taxa | Haplo | Human | Rat | Chick | Dog | Pig | Mouse‡ | No. non–blood meal clones |
|---------------------|-------------------|--------|------|-------|-------|-----|-------|-----|-----|--------|--------------------------|
| cytB                | T. protracta      | +      | M    | 8     | 1     | 2   | A     | A (4) | B   |        |                          |
|                     |                   |        |      |       |       |     |       |     |     |        |                          |
| 12S rRNA            | T. protracta      | +      | M    | 8     | 2     | 4   | A (4) | A (2) | B   | C      |                          |

†Vector species, T. cruzi infection status, collection location, number of clones sequenced, number and identity of taxa, and number of haplotypes represented in the clone sequences are indicated. Blank cells indicate clones were not found. For the cytB assay, the number of clones that were Triatoma spp. vector DNA or had uninterpretable sequences are indicated. The mouse-fed control (cytB assay) had 2 mouse haplotypes. Haplo, haplotypes; rat, woodrat; chick, chicken; ND, not determined because of low quality sequence data; –, negative; +, positive.
†Insects were collected by using light traps at Redington Road, Tucson, Arizona (R), and Escondido, CA (E), in 2007, and within the Arizona-Sonora Desert Museum, Tucson, AZ (M), in 2009. The light traps were in “wildness” (museum) and “sylvatic” (Redington Road and Escondido) habitats and not in human habitations.
‡Control.
§Triatoma spp.
clear. No one lives at the museum, but there is camping in the area.

Around Escondido, we found *T. protracta* bugs fed on humans, woodrats, and domestic chickens, according to the cytB assay. This assay amplified only vector DNA from 4/7 insects, which could mean it had been a long time since the last blood meal and thus the DNA was highly degraded. We detected only 1 blood meal source in the other 3 insects from California but found 2 woodrat sequences in a single insect. Both *T. rubida* bugs collected in California had fed only on humans; 2 unique human sequences from 2 clones from 1 insect suggest it had fed on 2 humans.

Compared with cytB, the 12S assay had better amplification and sequence quality and no recovery of insect vector DNA. Attempts to improve the cytB assay (e.g., higher annealing temperature) were unsuccessful, leading us to try the 12S assay, which had a smaller amplicon size and higher primer specificity for vertebrate DNA (13). Only mouse DNA was detected from the control bug that had fed on mouse in the laboratory (2), demonstrating the cytB assay worked well for fresh blood meals; however, for degraded DNA, 12S is a better assay.

Overall, cytB is more variable than 12S, producing more haplotypes, and thus can detect feeding on multiple individuals of the same taxon. Because identifying the source of blood meals depends on the availability of similar sequences in GenBank, another advantage of cytB is that GenBank contains 3–4× as many vertebrate sequences for comparison.

In conclusion, although allergic reaction from triatomine bites is well known (12), the high incidence of human blood meals in these bugs in our study suggests that the potential for human transmission of *T. cruzi* parasites might be greater than previously thought. Our assays using vertebrate primers and cloning PCR products may be especially useful for detecting unpredicted blood meal sources and multiple blood meals.
