OBJECTIVE Craniopharyngiomas have historically been resected via transcranial microsurgery (TCM). In the last 2 decades, the extended endoscopic endonasal (transtuberculum) approach to these tumors has become more widely accepted, yet there remains controversy over which approach leads to better outcomes. The purpose of this study is to determine whether differences in outcomes were identified between TCM and extended endoscopic endonasal approaches (EEEAs) in adult patients undergoing primary resection of suprasellar craniopharyngiomas at a single institution.

METHODS A retrospective review of all patients who underwent resection of their histopathologically confirmed craniopharyngiomas at the authors' institution between 2005 and 2015 was performed. Pediatric patients, revision cases, and patients with tumors greater than 2 standard deviations above the mean volume were excluded. The patients were divided into 2 groups: those undergoing primary TCM and those undergoing a primary EEEA. Preoperative patient demographics, presenting symptoms, and preoperative tumor volumes were determined. Extent of resection, tumor histological subtype, postoperative complications, and additional outcome data were obtained. Statistical significance between variables was determined utilizing Student t-tests, chi-square tests, and Fisher exact tests when applicable.

RESULTS After exclusions, 21 patients satisfied the aforementioned inclusion criteria; 12 underwent TCM for resection while 9 benefitted from the EEEA. There were no significant differences in patient demographics, presenting symptoms, tumor subtype, or preoperative tumor volumes; no tumors had significant lateral or prechiasmatic extension. The extent of resection was similar between these 2 groups, as was the necessity for additional surgery or adjuvant therapy. CSF leakage was encountered only in the EEEA group (2 patients). Importantly, the rate of postoperative visual improvement was significantly higher in the EEEA group than in the TCM group (88.9% vs 25.0%; p = 0.0075). Postoperative visual deterioration only occurred in the TCM group (3 patients). Recurrence was uncommon, with similar rates between the groups. Other complication rates, overall complication risk, and additional outcome measures were similar between these groups as well.

CONCLUSIONS Based on this study, most outcome variables appear to be similar between TCM and EEEA routes for similarly sized tumors in adults. The multidisciplinary EEEA to craniopharyngioma resection represents a safe and compelling alternative to TCM. The authors’ data demonstrate that postoperative visual improvement is statistically more likely in the EEEA despite the increased risk of CSF leakage. These results add to the growing evidence that the EEEA may be considered the approach of choice for resection of select confined primary craniopharyngiomas without significant lateral extension in centers with experienced surgeons. Further prospective, multiinstitutional collaboration is needed to power studies capable of fully evaluating indications and appropriate approaches for craniopharyngiomas. https://thejns.org/doi/abs/10.3171/2016.9.FOCUS16314

KEY WORDS craniotomy; endoscopic; transsphenoidal; craniopharyngioma; suprasellar; complications; outcomes; adult
Cranioopharyngiomas are midline suprasellar brain tumors that often extend superiorly into the third ventricle and are composed of benign epithelial tissue. These tumors are thought to derive embryologically from remnant cell rests after failure of the craniopharyngeal duct of Rathke’s pouch to entirely disappear logically from remnant cell rests after failure of the cranio-}

classically in the form of bitemporal hemianopia. Diagnosis and referral to neurosurgical surgery is often delayed because of the tumor’s slow growth and the insidious onset of symptoms, including headache, endocrine dysfunction, and visual disturbance, classically in the form of bitemporal hemianopia. Gross-total resection of these tumors represents the gold standard of treatment, although subtotal resection with adjuvant radiotherapy remains an alternative option when the tumor cannot be completely excised without placing the critical cerebrovascular structures at risk. The quality of life after resection is an important priority.

Cranioopharyngiomas occupy a critical central anatomical location close to the third ventricle, the optic chiasm and tracts, the internal carotid arteries and their branches, and the pituitary stalk. Historically, neurosurgeons have employed a variety of transcranial microsurgery (TCM) corridors for reaching and removing these tumors, including the anterolateral pterional and orbitozygomatic, anterior subfrontal and bifrontal, and transcallosal-transventricular approaches. All of these TCM approaches share the risk of brain retraction and, importantly, place the optic nerve between the surgeon and the tumor. The optic nerves must be manipulated for exposure of the tumor, and the superior pole of the mass is placed within the operative blind spot. These factors increase the risk of postoperative neurological deficits, including visual deterioration. Other complications include endocrinopathy and stroke.

Over the last decade, refinements in extended endoscopic endonasal approaches (EEEAs) have encouraged more surgeons to use this route. EEEA resection of craniopharyngiomas employs expanded transplanum craniocaudal access via transtuberculum, transplanum, and transclival osteotomies. EEEA is a sensible approach for a subchiasmatic lesion extending into the third ventricle as it allows for exploration via a subchiasmatic operative corridor. Importantly, the tumor is debulked, and the optic apparatus is decompressed early before the nerves are handled. In addition, the tumor is exposed along its long axis; therefore, extended operative working angles are created for maximizing tumor resection while minimizing surgical blind spots. Finally, brain retraction and manipulation is avoided. The increased rate of CSF leakage and the limited selection of tumors that are appropriate candidates for this approach are some of the drawbacks of this corridor. Tumors with lateral extension beyond the carotid bifurcation or with vascular encasement are considered poor candidates for EEEA. In addition, the required specialized expertise limits the use of the approach. To date, no study has specified the precise number of cases or training requirements to obtain the necessary experience to be successful in using these endoscopic approaches.

There is great heterogeneity in the operative care of craniopharyngiomas across different institutions, with limited evidence regarding the comparative benefits of TCM and EEEA routes. In 2012, Komotar et al. performed a meta-analysis of 88 retrospective case series to compare outcomes of TCM and EEEA for craniopharyngiomas. Since that time, only one single-institution series has compared the outcomes of TCM and EEEA in the hands of a single group of surgeons. The studies included in the meta-analysis and single-institution series included both primary and revision resections as well as noncraniopharyngioma suprasellar pathologies. There remains a lack of consensus and evidence regarding the benefits of TCM versus EEEA in the setting of primary resection. In the current study, we aimed to evaluate the outcomes of TCM and EEEA operations for primary resection of craniopharyngiomas in adults at our institution.

Methods

Institutional review board exemption through the Indiana University Office of Research Compliance Human Subjects Division was obtained for the planned retrospective review prior to initiating patient identification or chart review. The Indiana University Department of Pathology and Laboratory Medicine surgical case log was queried for all patients with a histopathological diagnosis of craniopharyngioma identified during the period from 2005 through 2015. Noncraniopharyngioma midline suprasellar histopathologies such as pituiticystoma, xanthogranuloma, meningioma, pituitary adenoma, glioma lymphoma, and germinoma were excluded from the search. Craniopharyngioma diagnoses before 2005 were excluded to pursue case-control matching in the groups. Pediatric patients (<18 years of age) were excluded.

Adults undergoing either TCM or an EEEA for recurrent tumors were excluded to avoid confounding bias in results. Preoperative MRI studies were evaluated to accurately determine anteroposterior, craniocaudal, and transverse dimensions of all craniopharyngiomas. Tumor volume was calculated assuming a roughly spherical tumor configuration where tumor volume in cubic centimeters (cm³) = (anteroposterior × craniocaudal × transverse)/2. Large-volume tumors greater than 16 cm³ (~2 SDs larger than the combined mean tumor volume of all included patients) were excluded to create a group of tumors that were most likely approachable via TCM and EEEA corridors. None of the included patients had significant lateral extension of their tumors that would have precluded EEEA in this study. One independent neurosurgeon skilled in both EEEA and TCM approaches reviewed the preoperative images and confirmed that these tumors were amenable to both approaches.

The physical clinic records and electronic medical record were reviewed for all included patients. Patients were divided into 2 groups depending on operative records indicating whether TCM (pterional, orbitozygomatic, bifrontal, or transcallosal) or an EEEA (transplanum/craniocaudal/
transtuberculum/transplanum) had been performed. Notation was made of postoperative closure technique in the EEEA group. As recurrent and revision procedures were excluded, no individual patient was represented in both groups of this study. Extent of resection (EOR) was based off of available postoperative imaging reports by an independent neuroradiologist; postoperative MRI studies were unavailable for 3 patients who underwent TCM. For these 3 patients, intraoperative evaluations of the operating surgeon were used. Reference to operative descriptions of the necessity to perform subtotal resection was documented. MRI reports and operative reports were also reviewed to determine tumor characteristics, including texture (solid, cystic, or mixed).

Patient preoperative records were analyzed to determine presenting symptoms, including headache, visual disturbance, diabetes insipidus (DI), or hypopituitarism. Postoperative hospital and clinic notes were reviewed for outcome data (hospital length of stay, seizures, wound infection, stroke/hemiparesis, CSF leakage, meningitis, permanent DI, hypopituitarism, hydrocephalus, hemorrhage, recurrence, perioperative mortality within 30 days, need for adjuvant therapy or revision surgery, and follow-up length). Visual outcomes were categorized as improved, stable, or deteriorated based on preoperative and postoperative visual field examinations. Chart review of otorhinolaryngological patient records lacked detailed quality scoring data ( sinonasal outcome test [SNOT-22]). The rhinologist, however, evaluated and documented the presence of nasal crusting, loss of sense of smell and taste, and persistent drainage during the postoperative follow-up visits in EEEA patients. As no objective data of sinonasal outcomes were measured, no statistical analysis for this metric was performed.

Statistical analysis between groups was performed to determine if significant differences existed between proportions or means of perioperative and outcome data. SPSS software (version 23, IBM Corp.) was used for all data analysis. Descriptive statistics were used to analyze patient demographics, presenting symptoms, perioperative complications, EOR, need for adjuvant therapy, and tumor characteristics. Continuous variables were described with means, medians, and interquartile ranges as appropriate, while categorical variables were presented as frequencies/percentages. Univariate comparisons were conducted using Student t-tests, chi-square tests, and Fisher exact tests. For all tests, p values < 0.05 were considered statistically significant.

Results
Patient Demographics

We identified a total of 33 histopathological diagnoses of craniopharyngioma at our institution between 2005 and 2015. Twelve cases were excluded by the established criteria, leaving 21 patients in the study (12 TCM and 9 EEEA operations) (Fig. 1). Both patients removed for size exclusion had undergone TCM operation as their approach. No significant demographic differences in mean patient age, sex, or presenting symptoms were identified. Visual disturbance represented the most prevalent presenting symptom in both groups, while headache was the second most common preoperative complaint (Table 1). No patient presented with isolated DI, but hypopituitarism was not uncommon.

Operative Techniques

Of the TCM cases, 75.0% were via a pterional approach and 8.3% each were via bifrontal, orbitozygomatic, and transcallosal approaches. Within the EEEA cases, all patients underwent a transsphenoidal/transtuberculum approach with tailored transplanum extension. In 88.9% of EEEA cases, closure used a combined underlay/overlay technique with a pedicled nasoseptal flap. The one case with a simpler closure technique (fat graft alone) without a pedicled nasoseptal flap did not result in CSF leakage postoperatively. In the first 6 years of our study, TCM was solely performed because of the absence of an anterior skull base–trained otorhinolaryngologist. After the arrival of a fellowship-trained rhinologist at our institution, the proportion of EEEA cases increased dramatically over time (Fig. 2).

Tumor Characteristics

Craniopharyngioma characteristics are enumerated in their entirety in Table 2. The preoperative tumor volumes were similar between surgical groups in our study, with no significant differences noted. Similarly, tumor consistency on MRI and intraoperative reports were without significant differences between the groups. Tumors in both groups uniformly exhibited suprasellar and retrochiasmatic extension without significant lateral extension beyond the suprachiasmoid internal carotid artery. The histological subtype noted on pathology reports were predominantly adamantinomatous in both the TCM and EEEA groups, while the papillary histopathology was uncommon and the mixed subtype only occurred once; no significant differences existed between the groups.

Postoperative Complications

Overall perioperative risk of any negative outcome was equivalent between groups (66.7% TCM vs 77.8% EEEA, p = 0.66). The complete listing of perioperative complications by group is tabulated in Table 3. Permanent DI represented the most frequent overall complication in both groups and affected approximately half of all patients without significant differences between the groups. Panhypopituitarism represented the second most common perioperative complication in our series, also with similar frequency between the groups. CSF leak only occurred within the EEEA cases with the difference trending toward but failing to reach significance (0.0% TCM vs 22.2% EEEA, p = 0.17). Recurrence, meningitis, stroke/hemiparesis, and wound infections were rare complications in our series, without significant differences between the groups. No patients in either group experienced documented perioperative seizures, hydrocephalus, postoperative hemorrhage, or perioperative mortality occurring within 30 days of the operation.

Visual Outcomes

Visual deterioration occurred only within the TCM
cases, and the difference did not achieve significance (p = 0.23; Table 4). The proportion of patients in each group who either maintained or improved their vision was without any statistical significant difference (75% TCM vs 100% EEEA, p = 0.23). While only 25% of TCM patients experienced improved visual outcomes, 88.9% of EEEA patients experienced improvement in postoperative vision, and this difference was determined to be statistically significant (p = 0.0075).

Other Outcome Measures
Additional outcome data are tabulated in their entirety in Table 5. The overall mean length of stay was shorter in the EEEA group than in the TCM group, but this parameter did not achieve significance. More variability in hospital length of stay was noted in the TCM group. Similarly, there was a shorter mean follow-up length in the EEEA group compared with the TCM group, which did not reach significance; again, there was a greater variability within the TCM group. A similar proportion of patients underwent gross-total resection as determined by postoperative imaging and intraoperative inspection; this factor did not reach significance among the 2 groups. Of the patients in whom subtotal resection was performed, a similar proportion went on to require adjuvant therapy in the form of radiotherapy and/or revision surgery without significant differences between these groups.

Discussion
Patient and Tumor Characteristics
Our study found no significant differences between TCM and EEEA patients with regard to average age, sex, or types or frequencies of presenting symptoms. Likewise,
baseline tumor characteristics including preoperative volume, histopathological subtype, and consistency were all similar without significant differences between the groups. These findings are similar to those reported by Jeswani et al. in their evaluation of outcomes of TCM and EEEA for craniopharyngioma resection. This homogeneity between surgical groups suggests that our outcomes data reflect differences deriving from the surgical approaches themselves rather than the inherent differences in the type of patient or tumor selected for one approach over the other. It is important to note that all revision/recurrence cases were excluded from our series in an effort to remove any confounding bias derived from increased difficulty in reoperation in a scarred or previously radiated operative field, previously existing injury to the critical structures, or preexisting permanent DI as a previous surgical complication.

Postoperative Endocrine Dysfunction

While no significant difference was noted in the proportion of our patients whose surgical outcomes were complicated by permanent DI, this did represent a frequent complication, affecting 50% of TCM patients and 55.5% of EEEA patients. With regard to permanent DI rates, the rate for TCM patients in our series fared similarly to that of 54.8% noted in the 2012 meta-analysis by Komotar et al. and the recent Jeswani et al. series, citing a permanent DI rate of 52.9% for TCM (no significant difference noted compared with their EEEA group). Other studies cited rates of postoperative permanent DI following TCM approaches ranging from 23%, 27.2%, 43%, to 50%. Our 55.5% postoperative rate of permanent DI in EEEA patients was comparable to the 48.1% rate cited

### Table 1. Demographic data regarding mean patient age, sex, and presenting symptoms

| Variable                | All Cases | TCM | EEEA | p Value |
|-------------------------|-----------|-----|------|---------|
| No. of cases            | 21        | 12 (57.1) | 9 (42.9) |         |
| Age in yrs              |           |     |      |         |
| Mean (SD)               | 50.1 (16.4)| 48.3 (16.3) | 52.4 (17.2) | 0.59    |
| Median (IQR)            | 53 (41.5–64.5)| 51.5 (40.5–62.5) | 59 (46.8–71.3) |         |
| Male sex                | 13 (61.9) | 7 (58.3) | 6 (66.7) | 1.00    |
| Presenting symptom      |           |     |      |         |
| Headache                | 11 (52.4) | 5 (41.7) | 6 (66.7) | 0.39    |
| Visual disturbance      | 18 (85.7) | 10 (83.3) | 8 (88.9) | 1.00    |
| DI                      | 0 (0)     | 0 (0) | 0 (0) |          |
| Hypopituitarism         | 7 (33.3)  | 4 (33.3) | 3 (33.3) | 1.00    |

IQR = interquartile range. Unless otherwise indicated values are expressed as number of cases (%).

**FIG. 2.** Bar graph demonstrating percentages of primary craniopharyngioma resections by TCM versus EEEAs at our institution from 2005 to 2015.
by Cavallo et al. in their 2014 series of 103 EEEA patients and the 44% rate found in the series of 12 adults by Jane et al.14 Our rate of DI in the EEEA group was notably higher, however, than the 27.7% rate cited in the meta-analysis by Komotar et al.,17 the 31.6% rate found in the Jeswani et al. series,19 and the 32.3% rate in the Koutourousiou series of 64 patients.19

Panhypopituitarism in our series was less common than permanent DI with rates of 16.7% in the TCM group and 33.3% in the EEEA group without the difference achieving statistical significance. Our rates were much lower than those reported in the meta-analysis by Komotar et al. of 48.1% and 47.1% for TCM and EEEA, respectively, and their intergroup difference also failed to achieve statistical significance.17 Our rates were also lower than those in the Jeswani et al. series of 38.2% and 42.1% for TCM and EEEA, respectively.19 Other reports of panhypopituitarism following TCM have cited rates similar to those of Komotar et al. and Jeswani et al. 1,9,29,33 Our EEEA panhypopituitarism rate of 33.3% was in line with those found by the Koutourousiou series rate of 37.5%19 and the Leng et al. series rate of 38%,20 and it was better than the Cavallo et al. rate of 46.2%.5

Visual Outcomes

We found a statistically significant difference in the rate of postoperative visual improvement between our EEEA and TCM groups (88.9% vs 25%, respectively; p = 0.0075). This difference exceeded the significant difference between EEEA and TCM groups reported in the Komotar et al. meta-analysis (56.2% vs 33.1%, respectively; p < 0.003).17 Our EEEA findings are similar to those published by Gardner et al. in their 2008 series in which 92% of patients demonstrated improved vision after EEEA.12 High rates of visual improvement following EEEA for craniopharyngiomas have been noted by others as well.5,11,26,30 The recent single-institution comparison of TCM versus EEEA by Jeswani et al. failed to demonstrate a statistically significant improvement in visual outcomes in their EEEA group.15

Visual deterioration occurred only in our TCM group, with 25% of patients experiencing some degree of visual decline; when compared with that of our EEEA outcomes, this result did not achieve significance (p = 0.23). This concern for higher risk of visual deterioration in TCM approaches is supported by the findings of the Komotar et al. meta-analysis where worsening vision was found in 11.3% of TCM cases versus only in 1.7% of EEEA cases (p < 0.003).17 Other studies reported similar visual decline rates after TCM of 14.3%9 and 12.8%.28 Our results add to the growing evidence among many institutions that EEEA is superior to TCM approaches with regard to limiting visual deterioration and in maximizing the chance of visual improvement.

The significant improvement in postoperative vision in the EEEA group can be explained by the immediate decompression of the optic apparatus via subchiasmatic removal of the tumor via the transnasal route. However, the transcranial corridor places the optic nerves between the surgeon and the tumor; this phenomenon increases the risk for manipulation of the optic apparatus and resultant visual decline observed in the TCM group.

Cerebrospinal Fluid Leakage

While there were no CSF leaks observed in our TCM group, our study was likely insufficiently powered to find a statistical difference considering the CSF leak rate of 22.2% in our EEEA group (p = 0.17). The Komotar et al. meta-analysis found a comparable CSF leakage rate of 18.4% for EEEA while the rate among the patients who

### Table 2. Tumor size, histopathological subtype, and consistency

| Variable                  | All Cases | TCM   | EEEA | p Value    |
|---------------------------|-----------|-------|------|------------|
| No. of cases              | 21        | 12 (57.1) | 9 (42.9) |            |
| Mean tumor vol in cm³ (SD)| 6.5 (5.1) | 7.8 (5.0) | 4.6 (4.7) | 0.16       |
| Pathological type         |           |       |      |            |

### Table 4. Postoperative visual outcomes

| Visual Outcome | All Cases (n = 21) | TCM (n = 12) | EEEA (n = 9) | p Value    |
|----------------|--------------------|--------------|--------------|------------|
| Improved       | 11 (52.4)          | 3 (25.0)     | 8 (88.9)     | 0.0075*    |
| Stable         | 7 (33.3)           | 6 (50.0)     | 1 (11.1)     | 0.16       |
| Deteriorated   | 3 (14.3)           | 3 (25.0)     | 0 (0)        | 0.23       |

Unless otherwise indicated values are expressed as number of cases (%).

* Statistically significant.
underwent TCM was only 2.6%; this difference was significant.\textsuperscript{17} Jeswani et al. also found a significant difference in their EEEA versus TCM CSF leakage rates at 26.3% and 0%, respectively.\textsuperscript{15} It is not surprising that CSF leakage is more likely to occur after EEEA as this approach opens a high CSF flow corridor between the third ventricle and the nasal cavity.

Our CSF leakage rate after EEEA is comparable to those in other studies evaluating EEEA for craniopharyngioma resection.\textsuperscript{11,19,30} The majority of our patients in the EEEA group underwent a skull base repair performed by an otorhinolaryngologist trained in endoscopic closure utilizing nasoseptal flaps. Institutions with high case volumes of EEEA and routinely utilizing nasoseptal flaps have reported decreasing rates of CSF leakage at 14%,\textsuperscript{15} 10.6%,\textsuperscript{19} and even as low as 4%,\textsuperscript{5} 3.8%,\textsuperscript{20} and 0%.\textsuperscript{14}

Other Complications

Complications such as wound infection, stroke/hemiparesis, and meningitis were too rare to provide grounds for determining statistical differences between groups, but the latter 2 outcome variables did occur only within the TCM group. None of our patients experienced postoperative hydrocephalus despite it being reported in 15.8% of EEEA patients by Jeswani et al.,\textsuperscript{15} 12.7% in EEEA patients by Koutourousiou et al.,\textsuperscript{19} and 15.8% in the Komotar et al. meta-analysis.\textsuperscript{17} Postoperative seizures, hemorrhage, and death within 30 days of surgery also did not occur in our series. For the Komotar et al. meta-analysis, the TCM group had a postoperative seizure rate of 8.5%, hemorrhage rate of 2.0%, and perioperative mortality rate of 3.2%; their EEEA group had a postoperative seizure rate of 0%, hemorrhage rate of 3.2%, and perioperative mortality rate of 1.9%.\textsuperscript{17} The overall risk of experiencing any complication in our series was not significantly different between groups (66.7% TCM vs 77.8% EEEA; p = 0.66). In comparison, Jeswani et al. found a higher risk of experiencing any adverse outcome in the TCM group of 79.4% and a lower EEEA risk of 52.6%.\textsuperscript{15}

Additional Outcome Data

There existed no statistically significant difference in the mean hospital length of stay between the surgical groups in our study. It should be noted, however, that less variability was observed in the EEEA group as evidenced by the smaller standard deviation of that group. While this might suggest a more predictable postoperative disposition for EEEA patients, there are numerous confounding variables, including the general preoperative health of the patient, insurance status, time of year of surgery, and availability of family to assist the patient at the time of discharge. Similarly, the mean follow-up time was without significant differences between surgical groups in our study; again, the EEEA group demonstrated much less variability by standard deviation. The same confounders and lack of power would impede a more in-depth analysis of follow-up data as well. Our mean follow-up time was notably shorter than the one published by the Komotar et al. meta-analysis of nearly 2000 days for TCM and 870 days for EEEA.\textsuperscript{17} This discrepancy most likely reflects the statewide neurosurgery referral and surveillance patterns for our institution as well as the relatively short period of time we have had multidisciplinary collaboration with a rhinologist available for EEEA cases (Fig. 2).

EOR was not significantly different between our surgical groups, with roughly the same percentage of cases achieving gross-total resection (58.3% TCM vs 55.5% EEEA, p = 1.00). It should be noted, however, that a limitation of this present study is a lack of review of our EOR by multiple independent neuroradiologists. Jeswani et al. also failed to demonstrate a significant difference in gross-total resection rates between TCM and EEEA cases.\textsuperscript{15} While our data do not support a difference in gross-total resection rates between TCM and EEEA, the Komotar et al. meta-analysis did find statistically higher rates in the EEEA group (66.9% vs 48.3%, p < 0.003).\textsuperscript{17} Our TCM rate of gross-total resection was comparable to those reported by other studies.\textsuperscript{9,29,31–33} Likewise, our rate of gross-total resection in EEEA patients was consistent with those reported by other authors,\textsuperscript{5,7,14,26} but some have reported gross-total resection rates as high as 86%\textsuperscript{20} and 89.6%\textsuperscript{12} for primary EEEA resections.

Regarding the proportion of our patients who underwent subtotal resection, there were no significant differences found between the TCM and EEEA groups. Furthermore, no significant difference existed in the ultimate

### Table 5. Additional outcome measures

| Variable                        | All Cases | TCM       | EEEA       | p Value |
|---------------------------------|-----------|-----------|------------|---------|
| No. of cases                    | 21        | 12 (57.1) | 9 (42.9)   |         |
| Mean hospital LOS in days (SD)  | 12.6 (12.0)| 14.4 (15.2)| 10.1 (5.4) | 0.38    |
| Mean follow-up time in days (SD)| 313.6 (688.1)| 375.6 (880.2)| 216 (178.9) | 0.57    |
| EOR                             |           |           |            |         |
| Gross total                     | 12 (57.1)| 7 (58.3)  | 5 (55.5)   | 1.00    |
| Subtotal                        | 9 (42.9) | 5 (41.7)  | 4 (44.4)   | 1.00    |
| Therapy required after subtotal resection | 6 (66.6) | 3 (60.0)  | 3 (75.0)   | 1.00    |
| Revision surgery                | 2 (33.3) | 1 (33.3)* | 1 (33.3)   | 1.00    |
| Adjuvant radiotherapy           | 5 (83.3) | 3 (100)   | 2 (66.6)   | 1.00    |

LOS = length of stay.

Unless otherwise indicated values are expressed as number of cases (%).

* One patient in the TCM group required adjuvant radiation that failed and the patient was ultimately treated with revision surgery via an EEEA.
need for further surgical or radiotherapy in the setting of subtotal resection. Our findings are corroborated by the Komotar et al. meta-analysis and the results of Jeswani et al., which similarly found no significant difference in the need for adjuvant radiotherapy or surgery when comparing TCM to EEEA. Recurrence only occurred in a single patient in each of our surgical groups. The rates of tumor recurrence in the meta-analysis Komotar et al. were 28.2% in the TCM group and 18.4% in the EEEA group, and, as in our study, no significant difference was noted. None of our patients in either group experienced recurrence when gross-total resection had been documented.

**Considerations and Limitations**

This present study focused its attention on cases of primary resection of craniopharyngioma in adult patients by TCM and EEEA at our institution in the last decade. In excluding pediatric and revision cases, we traded power in our study for comparing very similar groups of patients who underwent either surgical modality. We felt the reduction in power was a reasonable tradeoff to reduce confounding bias. For example, the EEEA data set in the Komotar et al. meta-analysis was composed of 42.9% revision cases while their TCM data set included only 18.3% revision cases, a difference that surprisingly did not achieve significance in their study. Jeswani et al. admitted to a significant difference between their TCM and EEEA proportion of revision cases (17.6% vs 42.1%, respectively; p = 0.05); this large difference between groups may have affected their outcome measures. In the same study, a closer evaluation of the preoperative tumor volume data shows that there was nearly a significant difference in the revision case tumor volumes between groups (4.3 cm³ TCM vs 10.6 cm³ EEEA; p = 0.06). By excluding revision cases, our present study avoids these confounders but risked not achieving the power necessary to find likely real outcome differences such as the higher CSF leak rate in EEEA cases and the proportion of postoperative visual deterioration in the TCM group.

As with any retrospective study, this current report is ultimately limited by the quality of data recorded in the clinical medical record. The lack of otorhinolaryngological quality data utilizing the SNOT-22 scoring system limited postoperative sinonasal complaints and hyposmia/anosmia rate evaluation in our study. However, to the best of our knowledge, none of our patients suffered from disabling forms of these symptoms. There also exists the real risk for selection bias inherent to any surgical retrospective series. In their comparison of TCM and EEEA for craniopharyngioma, Jeswani et al. found that 3 blinded neurosurgeon reviewers were only able to achieve complete concordance in surgical approach selection in 17% of 53 cases based on preoperative imaging; and they only agreed on the actual approach used in 11% of the 53 cases. By chance alone, these reviewers should have agreed 25% of the time and all selected the actual approach 12.5% of the time. Jeswani et al. therefore concluded that approach selection was more likely determined by the neurosurgeon’s level of expertise and personal preferences rather than because of preoperative imaging or other demographic characteristics. Ultimately, it would require a random-ized, prospective, dual-armed surgical trial to completely obviate the risk for selection bias in a comparison between TCM and EEEA for primary resection of craniopharyngioma. Because of infrequent disease incidence and ethical considerations, this ideal study is unlikely to occur.

**Conclusions**

The prevalence of neurological and otorhinolaryngological surgeons experienced in endoscopic endonasal approaches to the anterior skull base is growing, and this phenomenon has resulted in an increase in the proportion of craniopharyngiomas resected via EEEA at many centers. Most outcome variables between TCM and EEEA are similar. The multidisciplinary EEEA for primary resection of select craniopharyngiomas represents a safe alternative to TCM. We found a significantly higher rate of improved postoperative visual outcomes among EEEA cases when compared with those of TCM where there was a trend toward more visual deterioration. While differences in CSF leakage rates did not achieve statistical difference, CSF leaks were only observed within the EEEA group in our study. CSF leakage may prolong hospitalization or necessitate an additional trip to the operating room for repair, but its negative impact on long-term quality of life is likely to be lower than deterioration in visual outcomes. Large tumors and those with significant lateral extension may still be best managed by means of TCM approaches. While limited by low power, our preliminary results add to the growing evidence that EEEA may be considered the approach of choice for primary craniopharyngioma resection of select tumors in centers with experienced surgeons. Further prospective, multiinstitutional collaboration will be needed to power studies capable of fully evaluating which approach is most appropriate for craniopharyngiomas.
