Is resistance training intensity adequately prescribed to meet the demands of returning to sport following anterior cruciate ligament repair? A systematic review

Zackary William Nichols, Daniel O’Brien, Steven Gordon White

ABSTRACT

Objective To identify, critique and synthesise the research findings that evaluate the use of resistance training (RT) programmes on return to sport outcome measures for people following ACL repair (ACLR).

Design and data sources This systematic review included a comprehensive search of electronic databases (EBSCO health databases (CINAHL, MEDLINE, SPORTDiscus), Scopus and Pedro) performed in June 2020 and was guided by the Preferred Reporting Items for Systematic Reviews and Meta-Analyses checklist. Studies were appraised using the Downs and Black checklist.

Eligibility criteria Randomised and non-randomised controlled trials, longitudinal cohort studies and case series were considered for inclusion where an adequate description of the RT intervention was provided as a part of the study’s ACLR rehabilitation protocol. Articles that did not include outcome measures related to return to sport criteria were excluded.

Results Eleven articles met the inclusion criteria and were subjected to appraisal and data extraction. Study quality ranged from poor to excellent. RT intensity varied considerably among studies (between 5% and >80% of one repetition maximum). Only one identified study specifically investigated the effect of a low-intensity versus high-intensity RT protocol. The majority of studies reported participant outcomes that would not meet commonly used return to sport criteria.

Conclusion There appears to be considerable variation in the intensity of RT prescribed in research for people following ACLR. Furthermore, in most of the identified studies, RT protocols promoted muscle endurance and hypertrophy without progressing to strength or power-based RT. The findings of this review provide insight into potential factors limiting returning to sport and contributing to reinjury for people following ACLR.

INTRODUCTION

The incidence rate of primary ACL repair (ACLR) in Australia is the highest globally and continues to rise. Following surgery, rehabilitation is essential to ensure a return to full function by addressing postoperative strength and neuromuscular control deficits associated with reinjury. Resistance training (RT) is an integral component of an ACL repair (ACLR) rehabilitation programme. Re-injury following ACLR remains high, and associated physical deficits relating to return to sport criteria are commonly observed even after a return to sport.

What is already known

- Resistance training (RT) is an integral component of an ACL repair (ACLR) rehabilitation programme.
- Re-injury following ACLR remains high, and associated physical deficits relating to return to sport criteria are commonly observed even after a return to sport.
- RT intensities found in the ACLR rehabilitation literature do not align with strength and conditioning principles and are often not optimised to develop the desired neuromuscular qualities required of return to sport criteria. This may contribute to suboptimal prescription of rehabilitation programmes and poorly prepared athletes.

What are the new findings

- There is no consensus regarding optimal RT intensity (among other RT parameters) throughout ACLR rehabilitation literature.
- RT intensities found in the ACLR rehabilitation literature do not align with strength and conditioning principles and are often not optimised to develop the desired neuromuscular qualities required of return to sport criteria.
component. The utilisation of RT principles, while concurrently considering the stage of healing following ACLR, is a considerable challenge faced by clinicians and patients. Intensity is considered the primary component of RT to achieve the desired training effect. RT intensity is defined as the magnitude of load of a given exercise, often expressed as a percentage of an individual’s one repetition maximum (1RM). RT is optimised to improve different aspects of neuromuscular function depending on the prescribed intensity. The purpose of the exercise and corresponding intensity must be well understood to succinctly prescribe an RT programme following ACLR. Varying demands must be placed on the patient through RT to address deficiencies in muscle endurance, size, strength and power to restore the full neuromuscular function of the affected limb. Panariello et al. recommended a criteria-driven framework for rehabilitation following ACLR, breaking the rehabilitation process into distinct phases. The framework was based on the hierarchy of athletic development, recognising the needs of an ACLR patient as equal to the athlete preparing for sport.

Return to sport criteria following ACLR have been developed to objectively determine when a safe return to sport following ACLR is indicated. There is a consensus that passing the objective return to sport criteria is vital in reducing injury risk following ACLR; however, the association between current criteria and the risk of ACL graft injury is not yet clear. Kyritsis et al. found a fourfold increased risk of ACL graft rupture for those patients who did not pass the return to sport criteria. Additionally, Grindem et al. estimated an 84% lower knee re-injury rate among people who passed return to sport criteria. Following a meta-analysis of return to sport criteria, Losciale et al. advocated for stricter criteria, in particular, that 100% strength and function Limb Symmetry Index (LSI) scores should be used to improve the sensitivity of criteria in predicting rupture.

There appear to be confusion and a lack of consensus among physiotherapists surrounding ACLR rehabilitation. Physiotherapists have shown a lack of consistency when determining return to sport clearance, and Greenberg et al. reported that 56% of physiotherapists believed 5 months of rehabilitation was sufficient following ACLR. Yet, Toole et al. demonstrated that only 44% of patients had achieved an acceptable quadriceps LSI before gaining clearance to return to sport. These findings show an inadequate return to sport decision-making process and may suggest that suboptimal rehabilitation is being prescribed. Physiotherapists have also reported confusion surrounding the prescription and progression of exercises throughout ACLR rehabilitation. This confusion is likely accentuated by wide variability in rehabilitation protocols, most of which do not stress the importance of addressing deficits related to re-injury.

Although the causes of re-injury are multifactorial, an RT protocol that fails to address postoperative neuromuscular deficits is likely to be a crucial factor. Currently, there does not appear to be any consensus for the application and progression of RT intensity throughout the ACLR rehabilitation process to address postoperative neuromuscular deficits optimally. The objective of this systematic review was to identify, critique and synthesise the findings of research that has evaluated the effectiveness of RT programmes (where intensity has been defined) on physical return to sport outcome measures. (1) What is the quality of the literature that evaluates the effectiveness of an RT protocol (where intensity has been defined) following ACLR? (2) Does the intensity of RT described in ACLR rehabilitation literature align with recommended guidelines for RT? (3) Is the recommended intensity of RT, as detailed by the literature, sufficient to ensure that postoperative physical deficits are adequately addressed?

**METHODS**

This systematic review was guided by the Preferred Reporting Items for Systematic Reviews and Meta-Analyses checklist (2009) and registered with PROSPERO (ID: CRD42020136001).

**Data sources**

A comprehensive search of electronic databases was performed in June 2020. Databases included: EBSCO health databases (CINAHL, MEDLINE, SPORTDiscus), Scopus and Pedro. Two key concepts being ‘anterior cruciate ligament’ and ‘strength training’, and their alternative terms were identified and searched separately (table 1).

**Inclusion/exclusion criteria**

Studies were included if they were randomised or non-randomised controlled trials, longitudinal cohort studies or case series, where an adequate description of an RT intervention as a part of an ACLR rehabilitation protocol for 6 weeks or greater was provided. Exercise descriptors deemed necessary included the number of sets and

**Table 1** Search terms and Boolean operators

| Order of terms searched | Search terms and operators |
|-------------------------|---------------------------|
| Search 1 (S1)           | (ACL OR ‘anterior cruciate ligament’) AND (repair or ‘post-operative’ OR ‘post-operative’ OR surgery OR ‘post-surgery’ OR reconstruction) |
| Search 2 (S2)           | (strength* OR resistance OR weight* OR exercise OR intensity OR maximal) N5/W5 (train* OR program* OR protocol*) |
repetitions, the type of exercise and exercise intensity. Articles were excluded if they did not include outcome measures related to common objective return to sport criteria, did not report on primary data, were questionnaires and qualitative research, where full texts were not available, and were not published in a peer-reviewed journal or where an English version was not available.

Screening and study selection
Studies titles and then abstracts identified by the search were screened and read by the primary author. Full-text versions of each of these studies were reviewed to determine if the study met the inclusion and exclusion criteria. Reference lists from the identified studies were checked for possible additional studies not identified by the database search. The texts of all remaining articles were subject to quality appraisal and data extraction. Each study included in this systematic review was independently critiqued by the primary author and a second reviewer (both clinical physiotherapists). When all studies had been independently critiqued, the primary author and the second reviewer deliberated on individual results to reach a consensus on final scores.

Study quality appraisal and data extraction
A modified Downs and Black appraisal tool was used to assess the quality of selected articles. This tool is sufficiently reliable and valid for determining the methodological quality of randomised controlled trials and non-randomised trials. The modified tool has previously been used in other published systematic reviews. The total of the appraisal scores for each study was used to indicate the overall study quality, categorised as follows: poor (14 or below), fair (15–19), good (20–25) and excellent (26–28).

RESULTS
Study selection
Figure 1 illustrates the process undertaken to select the studies included for quality appraisal and data extraction. The search and screening process identified 11 articles for final quality appraisal and data extraction.

Quality of included studies
Studies varied in quality, with scores ranging from 13 to 26 out of a possible 28 (table 2). One study was categorised as excellent quality, four studies as good quality, four studies as fair quality and two studies as poor quality. Table 2 shows most studies scored well in reporting objectives, outcome measures, interventions and results. Studies commonly scored poorly on the items related to the inherent difficulties with researching this type of intervention and mainly affected the internal validity, such as a lack of blinding. Other items that were commonly scored poorly among studies affected the generalisability of results, including insufficient power due to a lack of participants, insufficient description of participant characteristics and facilities and equipment used not typically available to the general population.

Characteristics of included studies
Extracted data relating specifically to the research question, including RT intensities and the corresponding outcome measures associated with return to sport criteria, are summarised in the online supplemental table 1. Further information regarding the general characteristics of each reviewed study can also be found in the online supplemental table 2.

RT intensity
Seven of the studies expressed intensity as a percentage of 1RM, ranging from 5 to greater than 80% of 1RM. Five studies expressed intensity as a repetition maximum, ranging from 30RM to 6RM (<65% of 1RM–85% of 1RM). Six of the 11 studies reported interventions progressing in intensity from low to moderate high intensity in a periodised manner throughout the programme. The majority of RT interventions were optimised for the development of muscle endurance and hypertrophy between 60% and 80% of 1RM (>15RM~8RM). Perry et al.’s study was the only study to include RT intensities optimised to develop muscle strength (6RM or 85% of 1RM). The RT protocol described by Welling et al. stated intensities greater than 80% of 1RM in the final rehabilitation phase; however, it did not describe specifics.
Efficacy of interventions

**Strength**

Strength was measured in all studies except for the study performed by Perry et al. Strength was measured in all studies except for the study performed by Perry et al. The strength of either the quadriceps (knee extensors) or hamstrings (knee flexors) was assessed most commonly with an isokinetic dynamometer. Other measures relating to muscle strength that were evaluated included knee extensor muscle power, quadriceps peak torque normalised to body weight and extensor and flexor muscle endurance and ‘squat’ strength.

Seven of the studies measured the LSIs. Bieler et al. reported 98% (±4) LSI of the injured leg extensor power in the high-intensity RT group in comparison to 84% (±3) LSI in the low-intensity RT group following the intervention period (20 weeks post-ACLR), a statistically significant difference. Santos et al. assessed the subjects between 2 and 5 years post-ACLR and reported 111% and 128% quadriceps and hamstring LSIs, respectively, following the intervention, the highest among the included studies.

Quadriceps LSI among the remaining studies ranged from 62% (±18) to 94.1% (±14.6), while hamstring LSI results ranged from 72% (±11) to 97.9% (±7.5). Fukuda et al. and Welling et al. recorded the highest quadriceps LSI (94.1%±6 and 94.1±14.6) at approximately 6 and 10 months following ACLR, respectively. Welling et al. also recorded the highest hamstring LSI (97.9%±7.5). It should be noted that the study by Fukuda et al. included only participants who had undergone an ACLR using a hamstring tendon graft, while Welling et al. included participants who underwent a hamstring tendon or bone-patellar tendon graft.

**Function**

A variety of hop tests were used in six of the 11 studies. Bieler et al. reported 69% (±5) and 75% (±4) LSIs of the affected leg for a single and triple hop test in the high-intensity RT group, and 65% (±5) and 68% (±4) for the same measures in the low-intensity RT group following the intervention; these differences were not statistically significant. The single hop test results ranged from 65% (±5) to 95% (±8). Results of the triple hop tests varied between 68% (±4) and 94%, and results of the triple cross-over hop tests varied between 79% (±15) and 102%.

Two studies reported hop test results and included participants approaching a traditional return to sport period immediately following intervention completion (6 months post-ACLR). Both intervention groups in the study by Fukuda et al. achieved greater than 90% LSI or higher for the single hop test (92.3%±8.1 and 94.9±6.7) and cross-over hop tests (94.0±6.4 and 92.5±7.6). Risberg et al. reported the highest single hop and triple hop test LSI values in the neuromuscular training group (85%±11 and 89%±11, respectively) at 6 months post-ACLR, failing to achieve the return to sport criteria thresholds.

**Objectives**

Typically, the objectives of each study were focused on determining the effectiveness of different modes of RT, RT protocols or novel adjuncts to rehabilitation programmes against standard rehabilitation protocols, rather than explicitly investigating conventional RT as a cornerstone of the rehabilitation protocol. Only one study expressly investigated a high-intensity versus low-intensity RT protocol.

**Participants**

The mean age of participants across all studies ranged from 22 to 33 years old; the mean age of participants across all studies was 27 years old. Males and females were included in all studies; however, the majority of participants were male. Participants who underwent either a

hamstring tendon, quadriceps tendon or patella tendon graft ACLR were represented across studies.

**Intervention duration**

Intervention duration ranged from 6 to 41 weeks; participants completed two to three sessions per week. Interventions commenced between 1 and 12 weeks postoperatively, except Santos et al, who included participants between 2 and 5 years following ACLR. The majority of intervention periods were 12 weeks or greater in duration (n=8). Fukuada et al, Risberg et al and Welling et al represent the most complete rehabilitation protocols of included studies. Interventions commenced 1–2 weeks post-ACLR and were 25 weeks, 6 months and 10 months in duration, respectively. Aspects of the Risberg et al and Welling et al rehabilitation programmes were specifically designed to facilitate a return to sport.

**RT effect on graft laxity**

Five of the studies reviewed measured arthrometric graft laxity over the course of the intervention. All studies reported no significant differences in graft laxity between intervention groups or any deleterious increases in joint laxity as a result of the intervention. Furthermore, no studies reported significant injury over the course of the study periods.

**Adherence**

Three studies specifically described adherence to RT protocols, measured by the number of planned sessions completed. Adherence rates were generally high, between 85% and 100%. Welling et al's study was the only study to report a greater than 90% LSI of both hamstring and quadriceps muscle groups among the participants. However, comparison between graft types revealed quadriceps LSI values below 90% for people who underwent a bone-patellar tendon-bone graft at 10 months post-ACLR (98.3±8.4 and 87.1±12.5 quadriceps LSI for hamstring tendon and bone-patellar tendon-bone grafts, respectively). Additionally, no other study reported restoration of strength to 90% LSI or greater of the muscle group from which the ACL graft was harvested. In the case of the person returning to sport following ACLR, it is crucial that these people eventually progress to RT employed by the injury-free population at high intensities (90% of 1RM and greater). This requirement would help to ensure that an adequate level of physical conditioning is achieved to sufficiently prepare the athlete for the rigours of sport.

Periodisation allows a person to safely and effectively progress the RT protocol to higher intensities and facilitates maximal increases in strength. However, only five of the 11 studies used some form of linear periodisation, increasing intensity over the training period. The study by Welling et al provides the clearest example of periodisation. The RT protocol in this study included four phases and three distinct RT microcycles over 10 months; intensity was progressed from <50% of 1RM (muscle endurance) to between 60% and 80% of 1RM (muscle hypertrophy), and finally to greater than 80% of 1RM (strength) with an emphasis on a fast concentric phase (power). The findings show that RT protocols typically only progressed from intensities optimised to promote muscle endurance to intensities optimised for muscle hypertrophy, without a further progression to strength and power. Inadequate periodisation can hinder the patient’s performance in strength and function testing through a lack of progressive overload, limiting potential improvements. Furthermore, RT protocols without periodisation, particularly when training at intensities optimised for hypertrophy, have been suggested to hinder physical performance through overtraining induced physical and/or mental fatigue.

In athletic training, periodisation typically builds towards the athlete performing power-based RT. The development of power through RT is considered an essential characteristic of an RT protocol as it reflects the demands placed on an athlete’s neuromuscular system during maximal effort tasks. Not only is power a defining feature of the hop test battery and agility tests commonly used in return to sport criteria, injury mechanisms typically involve maximal effort tasks that require a high power output. Consequently, the patient must progress to power exercises to facilitate the greatest transfer of training effect. Welling et al's study was the only study included in this review to incorporate elements of

**DISCUSSION**

This systematic review shows the disparity between the intensity of RT protocols found in the ACLR rehabilitation literature and the recommended intensities required for optimal neuromuscular development. Furthermore, it demonstrates the large variances between studies in using RT parameters post-ACLR, particularly the intensity of exercises. Protocols used RT with intensities as low as 50% of 1RM and as high as 85% of 1RM, the latter representing the lower end of the strength development continuum and only constitutes moderate intensity. Protocols mostly incorporated RT intensities between 60% and 80% of 1RM in the mid and late stages of rehabilitation, sufficient to develop muscular endurance and stimulate hypertrophy. Two studies incorporated RT that would facilitate the development of maximal force production (strength). Perry et al prescribed exercises at 85% of 1RM and Welling et al reported prescribing exercises above 80% of 1RM in the final phase of rehabilitation.

RT at the intensities primarily observed in the included studies limits the potential for participants to develop maximal strength. Furthermore, these intensities fail to replicate the high physical demands required of a person during return to sport testing and of an athlete performing their sport. This factor may contribute to the results of the included studies reflecting research that demonstrates ACLR patients often fail to achieve return to sport criteria. Welling et al's study was the only study to report a greater than 90% LSI of both hamstring and quadriceps muscle groups among the participants. However, comparison between graft types revealed quadriceps LSI values below 90% for people who underwent a bone-patellar tendon-bone graft at 10 months post-ACLR (98.3±8.4 and 87.1±12.5 quadriceps LSI for hamstring tendon and bone-patellar tendon-bone grafts, respectively). Additionally, no other study reported restoration of strength to 90% LSI or greater of the muscle group from which the ACL graft was harvested. In the case of the person returning to sport following ACLR, it is crucial that these people eventually progress to RT employed by the injury-free population at high intensities (90% of 1RM and greater). This requirement would help to ensure that an adequate level of physical conditioning is achieved to sufficiently prepare the athlete for the rigours of sport.
RT that considered the development of power. Although Bieler et al. acknowledged the importance of power by measuring the effects of the intervention on leg extensor power, the protocol did not include RT optimised for power development. While a superior improvement in leg extensor power in the high-intensity compared with the low-intensity RT group was reported, a difference in hop test performance improvement was not seen. The lack of distinction between group’s hop test results may be explained by the RT protocol not progressing to power-based RT to facilitate a cross-over of training effect.

RT has been posited as the most important aspect of a rehabilitation programme following musculoskeletal injury. However, rather than focusing on the application of testing foundational elements of RT, ACLR research has focused on novel interventions, accelerated protocols, training adjuncts and different types of RT. The study carried out by Lepley et al. reflects this sentiment, which demonstrated that the addition of neuromuscular electrical stimulation to a 12-week RT protocol had no affect when comparing it to the RT protocol alone. Although current evidence-based guidelines promote the inclusion of RT from as early as 2 weeks post-ACLR, guidance for the application of RT variables including intensity is not defined. More focus should be placed on investigating the foundational elements related to RT, such as exercise intensity, in this population. The lack of attention on these elements in the literature reduces the importance of this aspect of ACLR rehabilitation and highlights an area that clinicians can improve.

Clinical practice

The findings of this systematic review include several implications that could affect clinical practice. The inconsistencies in RT protocols highlighted in this review reflect the existing research, which suggests that physiotherapists do not have the required information to develop suitable ACLR rehabilitation protocols. The variability of current ACLR rehabilitation protocols in clinical practice and concurrent high reinjury rates may be explained by the lack of consistency across rehabilitation protocols used in the literature.

A scarcity of literature exists that has investigated the protocols extending beyond 6 months post-ACLR. This is important for clinical practice because strength and function deficits commonly extend well beyond this time frame, suggesting that rehabilitation programmes should continue past this period. At 6 months post-ACLR, the graft progresses through the ligamentisation phase, has undergone considerable structural and biological changes and can tolerate higher external loads. Rehabilitation protocols completed before 6 months post-ACLR limit the opportunity to progress RT to higher intensities necessary for adequate physical preparation. The current literature leaves uncertainty for clinicians prescribing late-stage RT, which may be contributing to the discrepancy between clinicians’ expected rehabilitation duration and a return to sport. Evidence-based guidelines recommend rehabilitation continues for 9–12 months post-ACLR; however, the lack of literature accurately describing late-stage rehabilitation may be encouraging the premature completion of rehabilitation protocols and a subsequent return to sport.

Fear of damaging the ACL graft may cause clinicians to underprescribe RT intensity. Fears about graft injury, particularly in the early and middle phases of graft healing through poor or aggressive exercise prescription, have historically been a well-debated topic. Results reported by studies included in this review contribute to the notion that rehabilitation is safe and is not commonly the cause of complications following ACLR. No studies in this review reported serious injury or deleterious increases in graft laxity due to the exercise protocols. Bieler et al. provide the most direct reassurance about the safety of higher intensity RT during graft proliferation and early ligamentisation (12 weeks post-ACLR). No difference was found in knee joint laxity between high-intensity and low-intensity RT groups. Furthermore, the study by Perry et al. prescribed the highest RT intensities (6RM) observed in this review during graft proliferation (from 8 weeks post-ACLR), typically considered to be a vulnerable stage of graft healing, and reported no harmful effects to ligament laxity. While other parameters such as exercise type, range of movement and tempo should be considered when determining the safety of an exercise, intensities prescribed up to 6RM have been demonstrated to be safe in the early and middle stages of ACLR rehabilitation.

Future research recommendations

A future trial should investigate the efficacy of a 12-month, criteria-driven, periodised rehabilitation protocol. The protocol should incorporate foundational RT principles to maximise the cross-over effect, including RT intensities up to or greater than 90% of 1RM and a microcycle focused on power development. The rehabilitation protocol should take place in a standard gym setting and progress towards independent patient-led sessions. Outcome measures should include an accepted return to sport criteria test battery, exercise tolerance (pain and swelling), training volume, adherence, long-term reinjury reporting and level of return to sport achieved. Additional research investigating other foundational RT elements, particularly manipulating volume and frequency within a rehabilitation protocol, would provide further information to develop optimal RT programmes following ACLR.

Limitations

The review included studies where RT was not the primary variable being investigated. Because of this, the authors may have placed a reduced emphasis on the RT component of the protocol. The RT intensity used in these protocols may not be as applicable compared with the interventions that investigated RT as a primary...
variable. Furthermore, the specific outcome measures and interpretation of results were not used as inclusion criteria in this systematic review. This issue limited the ability to directly compare RT intensities and the efficacy of protocols between studies. Statistical analysis of the extracted data, such as analysing the relationship between RT intensity and outcome, was out of the scope of this systematic review. However, this could provide valuable information regarding the optimal prescription of RT intensity post-ACL.

CONCLUSION
This systematic review highlights an area of ACLR rehabilitation that merits more high-quality research so that physiotherapists are better equipped to manage the patients successfully. There is currently no universally accepted best practice guideline for the prescription of RT following ACLR despite RT being a cornerstone of rehabilitation. Available literature detailing RT intensity within ACLR protocols is inconsistent, incomplete and mostly not aligned with recommended RT principles. Optimisation of the prescription of RT for people following ACLR could lead to improvements in strength and functional outcomes and possibly reduce reinjury rates. Recent ACLR rehabilitation research incorporating RT principles and emphasising the importance of RT has provided promising results; however, further research is required to develop guidelines to improve clarity, and in particular, to identify optimal RT variables in this population.

\(^a\) LSI unless unit otherwise specified  
\(^b\) not specified if 6RM  
\(^c\) LSI comparison between pre-intervention non-injured leg and post-intervention injured leg  
\(^d\) Approximate weeks stated. Progression through stages of training varied depending on the individual (up to 4 weeks)  

**Note:** In studies where only the raw data for return to sport outcome measures were reported, LSI’s were calculated where possible; otherwise, percentage increases have been provided.

**Abbreviations:** PT, patellar tendon; \(^{\circ \cdot 1}\), degrees per second; \%, per cent; +, and; HI, high intensity; LI, low intensity; HT, hamstring tendon; QT, quadriceps tendon; CON, concentric; ECC, eccentric; ECC+, eccentric overload; EOKC/LOKC, early/late start open kinetic chain; OKC, open kinetic chain; CKC, closed kinetic chain; kg, kilograms; Ext, Extension; Flx, Flexion; ST, strength training; lb-ft, pounds per feet; mo, months; NM/kg, newton-meters per kilogram; NT, neuromuscular training; ↑, increased/improved; N, neuromuscular electrical stimulation; post-op, post-operative; Quads PT/BW, quadriceps peak torque normalised to bodyweight; RM, repetition maximum; SH, single-hop; TH, triple hop; TCH, triple crossover hop

|                       |                                                                           |                               |                   |                                                                                      | No difference between the groups for any outcome measurements at 3 months           |
|                       |                                                                           |                               |                   |                                                                                      | No difference in muscle strength variables                                         |
|                       |                                                                           |                               |                   |                                                                                      | Decline in quads strength and hop tests from pre-op period to 6 months post-op     |

| Study | Objective | Downs and Black Score | Participants | Duration | Exercise Parameters | Outcome Measures | Results |
|-------|------------|------------------------|--------------|-----------|----------------------|------------------|---------|
| Perry | Compare the effects of a CKC versus an OKC training regimen on knee joint laxity and function post ACLR | 20 - Good, 37m/12f, 33yo (mean) CKC group - 811 days from injury to surgery OKC group – 1340 days from injury to surgery | 2 sessions per week, 6 weeks | Wk 1-3: 3 x 20 reps, 20RM Wk 4-6: 3 x 6 reps 6RM | Knee joint laxity Single, vertical, cross-over hop tests. Hughston clinic questionnaire ROM Knee circumference | No difference in knee laxity between groups | No difference in self-reported function or functional hop tests between groups |
| Risberg | Determine the effect of an NT program vs a strength program on knee function following ACLR | 22 - Good, 47m/27f, 28.4yo (mean) Injury occurred less than 3 years before surgery | 2-3 sessions per week, 6 months | Phase 3: 3 x 12-15 reps progressing to 3 x 8-12 reps at 50-80% 1RM Phase 4: 3 x 6-8 reps | Cincinatti Knee Score SF36 VAS pain and knee function Knee flx, ext strength Balance Proprioception Single, triple hop test, stair hop test | 91% adherence in ST group. 71% adherent in NT group (80% or > attendance) | No difference in knee joint laxity between groups at 6 months | No difference between the groups for any outcome measurements at 3 months | No difference in muscle strength variables | Decline in quads strength and hop tests from pre-op period to 6 months post-op |
| Study | Protocol Details | Results | Notes |
|-------|----------------|---------|-------|
| Santos et al., 2018 | Correlate possible gains in knee extensor and flexor torque generated by isokinetic training with hop tests post-ACLR | 14 - poor | Knee ext strength deficit in affected leg at pre-training |
| | 16n 2-5 years post-op | 2 sessions per week, 12 weeks | Knee ext strength deficits remained post-training |
| | 3 x 10 reps, 10RM, 3-minute rest between sets | Knee ext and flexor strength | ↑ in knee flex strength post-training compared with knee ext |
| | | Single, triple, crossover, figure 8 hop tests | SH, TH and F8 tests ↑ compared with pre-training |
| | | | Moderate correlation between knee ext strength and single hop for AL, strong correlation for NAL |
| | | | Moderate correlation between knee flex strength and SH |
| Welling et al. 2019 | Compare results of a RT protocol for soccer players after ACLR with healthy controls | 15 – fair | 4 months post-ACLR quads strength weaker than control |
| | 38m 24.2yo (mean) 2 weeks post-op | 2.6 sessions (mean) per week, 10 months | 7 months post-ACLR no difference in quads or hamstring strength compared to control |
| | 2 x 15-25 reps (<50% 1RM) | Phase 2: 2 x 15-25 reps (<50% 1RM) & 2 x 15-25 reps (60-80% 1RM) & 2 x 15-25 reps (<50% 1RM) | 10 months post-ACLR hamstring strength greater than control |
| | | Phase 3: 2-4 x 8-10 reps (60-80% 1RM) & 2 x 15-25 reps (<50% 1RM) | 10 months post-ACLR 65.8% passed quads & 76.3% passed hamstring LSI>90% |
| | | Phase 4: 5 x 3 reps (>80% 1RM) & 2 x 15-25 reps (<50% 1RM) & 2 x 15-25 reps (<50% 1RM) | |

Abbreviation: °·s⁻¹, degrees per second; %, percent; +, and; >, greater than; ACL-QoL, anterior cruciate ligament quality of life; WBV, whole body vibration; Sig., Significant; RCT, randomised controlled trial; m, male; f, female; yo, years old; flx, flexor; ext, extensor; RT, resistance training; HI, high intensity; LI, low intensity; ↑, increased/improved; CON, concentric; ECC, eccentric; ECC+, eccentric overload; CSA, cross-sectional area; MCSA, muscle cross-sectional area; FCSA, fascicle cross-
sectional area; PT, patellar tendon graft; ST, semitendinosus tendon graft; mm, millimetres; MHCneo, neonatal myosin heavy-chain (measure of muscle regeneration/remodelling); NMES, neuromuscular electrical stimulation; OKC, open kinetic chain; CKC, closed kinetic chain; EOKC/LOKC, early/late start open kinetic chain; NMES, neuromuscular electrical stimulation; RTP, return to play; SR, standard rehabilitation; Pre-op, pre-operative; Post-op, post-operative; QAF, quadriceps activation failure; ROM, range of movement; NT, neuromuscular training; s, seconds; ST, strength training; AL, affected limb; NAL, non-affected limb; Reps, repetitions; SH, single hop; TH, triple hop; F8, figure 8 hop
