Composite Vectorlike Fermions

September 4, 2014

We study a dynamical mechanism that generates a composite vectorlike fermion, formed by the binding of an $N$-tuplet of elementary chiral fermions to an $N$-tuplet of scalars. Deriving the properties of the composite fermion in the large $N$ limit, we show that its mass is much smaller than the compositeness scale when the binding coupling is near a critical value. We compute the contact interactions involving four composite fermions, and find that their coefficients scale as $1/N$. Physics beyond the Standard Model may include composite vectorlike fermions arising from this mechanism.

1. Introduction

All known elementary fermions are chiral, so that their masses arise as a consequence of electroweak symmetry breaking. By contrast, vectorlike fermions have the same gauge charges for left- and right-handed components, so that their Dirac mass terms are present from the outset in the Lagrangian. Thus, it is natural to expect that vectorlike quarks or leptons, if they exist, are heavier than the Standard Model (SM) fermions. Vectorlike fermions are the subject of intensive searches at the LHC [1].

Vectorlike fermions are a key element within various strongly coupled theories for physics beyond the Standard Model (SM). Amongst these are the Top-seesaw theory [2], where a composite Higgs boson [3, 4] arises from the binding of a vectorlike quark to the top quark, models where the Higgs doublet is a pseudo-Nambu-Goldstone boson (pNGB) [5, 6], models of extra dimensions with bulk fermions [6, 7], and Little Higgs models [8] where vectorlike quarks cancel the quadratic divergence due to the top quark. In some of these theories the vectorlike fermions are thought to be bound states, but usually there is no precise description of what are their constituents, or what is the binding interaction responsible for these composite fermion fields.

Here we study a dynamical model of composite vectorlike fermions. We start with a dimension-6 interaction between a complex scalar and an elementary chiral fermion, both transforming in the fundamental representation of a global $SU(N)$ symmetry. The dimension-6 interaction may be induced by heavy gauge boson exchange, similarly to coloron exchange [9] in top condensation models [10, 11, 12]. Factorizing the interaction into spin-1 auxiliary fields, which at low energy acquire kinetic terms, we find that an $SU(N)$-singlet composite Dirac fermion forms; its right- (left-) handed component is an $s$- ($p$-) wave bound state of the elementary fermion and scalar. We solve this “Composite Vectorlike Fermion” (CVF) model in the large $N$ limit, deploying the “block-spin” renormalization group (RG) [11]. A model of this type was considered long ago [12] for describing the SM quarks and leptons as composite fields.

Near a certain critical coupling the Dirac bound state becomes much lighter than the compositeness scale. Although the Dirac mass vanishes at criticality, there is no associated chiral symmetry in this limit, due to the asymmetry between the dimension-4 and -5 operators producing the $s$- and $p$- wave components, respectively.

Large contact interactions have often been suspected of being associated with fermion compositeness [13]. Using the large-$N$ limit of the CVF model, we compute the effective interactions involving four composite fermions, and find indeed large coefficients; however, these coefficients scale as $1/N$, and thus become perturbative for very large $N$.

The CVF model has features in common with the Nambu-Jona-Lasino (NJL) model [14], which describes a spin-0 bound state, composed of a right-handed fermion, and a left-handed anti-fermion. The attractive interaction which drives the formation of the bound state is a chirally-invariant 4-fermion interaction, which may be viewed as the relic of a coloron exchange [9]. The leading effects of the interaction can be treated in large-$N$ approximation and generate a composite scalar whose mass depends upon a dimensionless coupling. As this approaches a critical value from below, the composite field becomes lighter, approaching masslessness. Above critical coupling the bound state acquires a vacuum condensate, the fermions acquire masses $m_f$ and pNGBs appear. There is also a Higgs boson of mass $2m_f$ in the broken phase in the large-$N$ approximation [15]. The analysis can be improved by use of the block-spin RG [11].

Although in the minimal CVF model the composite fermion is a gauge singlet, it is easy to give its constituents charges under the SM gauge group and to obtain composite vectorlike quarks or leptons, as often employed in theories beyond the SM. We view this CVF model as a “dynamics” which can serve as the kernel of various composite models of fermions, including partially-composite SM quarks and leptons [15] and descriptions of heavy-heavy-light baryons.
2. Composite fermion model

Consider a chiral fermion, \( \psi_L \) and a complex scalar, \( \phi \), which transform in the fundamental representation of a global \( SU(N) \) symmetry. We postulate a Lagrangian of the form

\[
\mathcal{L} = \mathcal{L}_0 + \mathcal{L}_{\text{int}},
\]

where the free-fields Lagrangian is

\[
\mathcal{L}_0 = i \bar{\psi}_L \not{\partial} \psi_L + \partial_\mu \phi^\dagger \partial^\mu \phi - M^2 \phi^\dagger \phi,
\]

and the interaction terms are

\[
\mathcal{L}_{\text{int}} = -\frac{g^2}{\Lambda^2} \left( \bar{\psi}_L \gamma^\mu T^a \psi_L \right) \left( i \phi^\dagger \partial_\mu T^a \phi \right).
\]

where \( T^a \) are the generators of \( SU(N) \), and for the moment \( \Lambda \) is a momentum space cut-off on the loop integrals, with \( M_\phi \ll \Lambda \). The notation in Eq. (3) is chosen to suggest that this term may be generated by the exchange of a gauge boson of coupling \( g \) and mass \( \Lambda \).

Using the color Fierz identity to leading order in \( 1/N \),

\[
T^a_{ij} T^a_{kl} = \frac{1}{2} \left( \delta_{il} \delta_{kj} - \frac{1}{N} \delta_{ij} \delta_{kl} \right) \approx \frac{1}{2} \delta_{il} \delta_{kj},
\]

Eq. (3) becomes

\[
\mathcal{L}_{\text{int}} \approx \frac{ig^2}{2\Lambda^2} \left[ \bar{\psi}_L \phi \right] \left[ \left( i \phi^\dagger \right) \psi_L \right] + \text{H.c.}
\]

where fields written within a pair of brackets, \([...]\), have their \( SU(N) \) indices contracted together.

The interaction term can be factorized \[12\] by introducing a static \( SU(N) \)-singlet Dirac fermion, \( \chi \), as follows:

\[
\mathcal{L}_{\text{int}} = \bar{\tilde{L}}_{\phi \chi} - \Lambda \chi \chi + O(1/N),
\]

where

\[
\bar{\tilde{L}}_{\phi \chi} = i \frac{g}{\Lambda} \bar{\psi}_L \left( \delta \phi \right) \chi_L - \frac{g}{2} \chi_R \phi^\dagger \psi_L + \text{H.c.}
\]

Integrating out \( \chi \) we recover Eq. (3) in the large-\( N \) limit. Therefore, we can view Eqs. (6) and (7) as the form of the interaction at the scale \( \Lambda \), which can then be evolved downhill in scale as \( \mu \ll \Lambda \).

Note that the choice of the couplings and mass of \( \chi \) at this stage is somewhat arbitrary, due to our freedom to rescale \( \chi_L \) or \( \chi_R \). Momentarily, the \( \chi \) fields will develop kinetic terms which will ultimately be canonically normalized, fixing the coupling normalizations.

3. Low-energy effective theory

The low-energy effective Lagrangian may be derived most expeditiously by means of the block-spin RG. In the case of the NJL model, the block-spin RG has been developed in \[11\]. Here we view Eq. (6) as the effective Lagrangian of the theory at a mass scale \( \Lambda \). To derive the effective Lagrangian at a lower scale \( \mu \), where \( \Lambda > \mu > M_\phi \), we integrate out the field modes of momenta \( \Lambda \geq k \geq \mu \). For the factorized CVF model of Eq. (6), this yields the effective Lagrangian at scale \( \mu \):

\[
\mathcal{L}(\mu) = \mathcal{L}_0 + \bar{\tilde{L}}_{\phi \chi} + Z_L \bar{\chi}_L \not{\partial} \bar{\chi}_L + Z_R \bar{\chi}_R \not{\partial} \bar{\chi}_R - \bar{m}_\chi \bar{\chi}_\chi,
\]

where we neglected operators of dimension 6 or higher. The \( \chi_L \) and \( \chi_R \) fields have acquired kinetic terms from the first diagram of Fig. 1 (the leading-\( N \) contribution), and thus have become dynamical fields. Their wavefunction renormalizations are given for \( M_\phi \ll \mu \) by

\[
Z_R = \frac{\kappa N}{32\pi} \ln \left( \frac{\Lambda^2}{\mu^2} \right),
\]

\[
Z_L = \frac{\kappa N}{4\pi} \left( 1 - \frac{\mu^2}{\Lambda^2} \right).
\]

The matching coefficient \( \eta \), of order one, depends on the procedure of cutting off the quadratic divergence in \( Z_L \); integrating over the loop momentum \( k^\mu \) (indicated in Fig. 1), with integration limits \( \mu \leq k \leq \Lambda \), gives \( \eta = 1 \). We defined the coupling constant

\[
\kappa \equiv \frac{g^2}{4\pi}.
\]

The Dirac mass of Eq. (5), arising from the second diagram of Fig. 1, is given in units of \( \Lambda \) by

\[
\tilde{m}_\chi = \frac{\kappa N}{8\pi} \left[ 1 - \frac{\mu^2}{\Lambda^2} + O \left( \frac{M^2}{\Lambda^2} \ln \left( \frac{\mu^2}{\Lambda^2} \right) \right) \right].
\]

It is useful to compare the NJL model side-by-side with the present scheme. First, \( Z_R \) is a conventional log-running result for an NJL type theory, \emph{e.g.}, of a composite Higgs \[11\]. In NJL an auxiliary scalar field, \( H \) (a Higgs field), is introduced to factorize a 4-fermion interaction, in analogy to the auxiliary fermion field \( \chi \) in our CVF model. Applying the block-spin RG to the NJL model, one obtains an induced kinetic term for \( H \) with a logarithmic wave-function renormalization constant \( Z_H \), in analogy to \( Z_R \) in Eq. (9).
The induced kinetic terms in NJL always vanish as \( \mu \to \Lambda \) and this is normally referred to as the “compositeness matching conditions.” The \( \chi_R \) kinetic term is generated by a dimension-4 interaction, \( \xi_R \phi^\dagger \psi_L \), so that the dynamical \( \chi_R \) field may be viewed as an s-wave bound state of \( \phi \) with \( \psi \), just as \( H \) is an s-wave bound state of \( \psi \) in the top-condensation theory [11].

Second, the wave-function renormalization constant for the composite \( \chi_L \) field, \( Z_L \), has the behavior in the block-spin RG of quadratic running in scale \( \mu \), analogous to the Higgs boson mass in top condensation. It arises from two insertions of the dimension-5 vertex \( \bar{\psi}_L (\phi \phi) \chi_L \) (see the first diagram of Fig. 1), hence the quadratic divergence occurs up to the cut-off \( \Lambda \). The exact result for \( Z_L \) is sensitive to how the theory is cut-off in detail. A precise determination of the coefficient \( \eta \) is really a matching condition of the low-energy theory onto a realistic high energy theory, such as a coloron model. This is typical for a quadratic or higher divergence, since the divergence is emphasizing the short-distance limit of the theory. This means that \( \chi_L \) enters the theory as a p-wave bound state, and the quadratic vanishing of \( Z_L \) as \( \mu \to \Lambda \) is indicative of the faster short-distance vanishing of the wave-function for the p-wave.

Finally, the Dirac mass \( \tilde{m}_\chi \) is also a quadratic divergence associated with the second diagram of Fig. 1. The analogous quantity in conventional NJL is the squared mass, \( M_H^2 \), for the composite H field. As \( \mu \to \Lambda \) we see that \( \tilde{m}_\chi \to \Lambda \), i.e., we map back onto the original factorized effective Lagrangian.

4. Physical fields and critical behavior

We can pass to canonical normalizations for the \( \chi \) fields by the scaling redefinitions

\[
\chi_R \to \sqrt{Z_R} \chi_R \quad \chi_L \to \sigma \sqrt{Z_L} \chi_L ,
\]

where \( \sigma = \pm 1 \) is introduced for later convenience. The effective Lagrangian at the scale \( \mu \) becomes

\[
\mathcal{L}(\mu) = \mathcal{L}_0 + \mathcal{L}_{\phi \chi} + \bar{\chi} \gamma^\mu \chi - m_\chi \bar{\chi} \chi ,
\]

with interaction terms

\[
\mathcal{L}_{\phi \chi} = \frac{i g}{\Lambda \sqrt{Z_L}} \bar{\psi}_L (\phi \phi) \chi_L - y_\chi \bar{\chi} \chi_R \phi^\dagger \psi_L + \text{H.c.} .
\]

The Yukawa coupling from the second term of \( \mathcal{L}_{\phi \chi} \) is given by

\[
y_\chi = \frac{g}{2\sqrt{Z_R}} = \frac{4\sqrt{2}}{\sqrt{N \ln (\Lambda^2/\mu^2)}} .
\]

This is the coupling of the \( \chi_R \) fermion to its constituents, so it is large, blowing up as expected at the compositeness scale \( \Lambda \). The Yukawa coupling becomes perturbative only at scales \( \mu < 10^{-5} \Lambda \), since the expansion parameter is \( g^2 N/(4\pi) = 4\pi/\ln(\Lambda/\mu) \).

The physical \( \chi \) mass, which enters Eq. (13), evaluated at the scale \( \mu \gg M_B \) is

\[
m_\chi = \sigma \frac{\tilde{m}_\chi}{\sqrt{Z_L Z_R}} = \sigma \Lambda \left( \frac{\kappa_c}{\kappa} - 1 + \frac{\mu^2}{\Lambda^2} \right) \left[ \eta \left( \frac{1}{2} \frac{\mu^2}{\Lambda^2} \ln \left( \Lambda^2/\mu^2 \right) \right) \right]^{-1/2} ,
\]

where we kept the dependence on the matching coefficient \( \eta \) introduced in Eq. (9). The behavior of this Dirac mass as \( \mu \to 0 \) is controlled by the critical coupling constant

\[
\kappa_c = \frac{g^2}{4\pi} = \frac{8\pi}{N} .
\]

For the weak-coupling case, \( \kappa < \kappa_c \), the composite fermion decouples \( m_\chi > \Lambda \), so the low-energy physics includes just \( \psi_L \) and \( \phi \).

For \( \kappa > \kappa_c \), the Dirac mass becomes much smaller than \( \Lambda \) for \( \mu \ll \Lambda \). This is not surprising, since the analogue behavior occurs in the conventional NJL model. We are essentially tuning a large hierarchy as \( \kappa \to \kappa_c \), and an approximately scale-invariant theory near the critical coupling.

In a conventional NJL model the behavior of the bound state boson mass, \( M_H^2 \), as \( \mu \to 0 \) determines the criticality of the model. If \( M_H^2 < 0 \) for \( \mu \to 0 \), then the composite Higgs field acquires a VEV. The critical coupling of NJL is that value for which \( M_H^2 = 0 \) as \( \mu \to 0 \).

In the CVF model at the exact critical value we have \( m_\chi \to 0 \). This is not, however, a chirally invariant theory, since the original interactions of the full theory violate the chiral symmetry of \( \chi \). Nonetheless, the effective Lagrangian does contain the massless fields \( \chi_R \) and \( \chi_L \). If one naively discards the “irrelevant” operator of \( \mathcal{L}_{\phi \chi} \), i.e., the first term of Eq. (14), in this limit, then we would have a true chiral fermion.

For \( \kappa > \kappa_c \), the Dirac mass becomes negative at scales \( \mu < \Lambda \). At the exact scale \( \mu_0 \) with \( m_\chi(\mu_0) = 0 \),

\[
\mu_0 = \Lambda \left( 1 - \frac{\kappa_c}{\kappa} \right)^{1/2} ,
\]

the full chiral symmetry of \( \chi \), \( U(1)_L \times U(1)_R \), is broken only by the \( \mathcal{L}_{\phi \chi} \) interactions of Eq. (14). It is thus possible to redefine the \( \chi_L \) and \( \chi_R \) fields by arbitrary complex phases, with the only effect being a change in the relative phase between the two terms of \( \mathcal{L}_{\phi \chi} \). In order to keep \( m_\chi(\mu) \geq 0 \) at all scales, we redefine \( \chi_L \to -\chi_L \) at scales \( \mu < \mu_0 \). In other words, the sign introduced in Eq. (12) is \( \sigma = +1 \) for \( \mu > \mu_0 \), and \( \sigma = -1 \) for \( \mu < \mu_0 \). This means that the RG evolution of \( \sigma(\mu) \) is proportional to the step function centered at \( \mu_0 \). The dependence of \( m_\chi \) on \( g/g_c \) is shown in Fig. 2.

5. Four-fermion interactions

The Lagrangian at scale \( \mu \), \( \mathcal{L}(\mu) \) includes operators of dimension-6 or higher, not shown in Eq. (8). Particularly
important among those are 4-χ terms. Large contact interactions of this type have often been suspected of being associated with fermion compositeness [15]. In our dynamical model, the coefficients of the operators involving four composite fermions can be computed in the large $N$ limit.

A peculiar 4-χ term is the one involving only right-handed fields, because it is generated only by the dimension-4 vertex involving the massless fermion $\psi_L$ (see the second term of $\mathcal{L}_{\psi\chi\chi}$). As a result, its coefficient is infrared divergent, instead of being suppressed by $\Lambda^2$. Performing the loop integral shown in Fig. 3, we find the following operator involving $\chi_R$ (with canonically normalized kinetic term):

$$\frac{-8\pi^2}{N(\mu^2 + M_\phi^2)} \left[ \ln \left( \frac{\Lambda^2}{\mu^2 + M_\phi^2} \right) \right]^{-2} (\chi_R \gamma_\mu \chi_R)^2 , \quad (19)$$

for $\Lambda^2 \gg \mu^2, M_\phi^2$. Note that the infrared divergence is cut-off either by $M_\phi$ or by the scale $\mu$ where the coefficient is evaluated (a physical value for that is $\mu = m_\chi$).

The other 4-χ operators are given by

$$\frac{8\pi^2}{N\eta\Lambda^2} \left[ 2(\chi_R)^2 + (\chi_L \gamma_\mu \chi_L)(\chi_R \gamma_\mu \chi_R) - \frac{\eta'}{4\eta} (\chi_L \gamma_\mu \chi_L)^2 \right] \quad (20)$$

Here we have included a matching coefficient $\eta'$ (of order one) in the quadratically divergent loops, in addition to the factor of $\eta$ from $Z_L$. Cutting off the loop integral at $\Lambda$ gives $\eta' = 1$.

The chiral symmetry breaking in these terms is a consequence of the structure of $\mathcal{L}_{\phi\psi\chi}$, shown in Eq. (14). As expected, the coefficients of these contact terms in units of $\Lambda^{-2}$ include a large factor of order $(4\pi)^2$. Nevertheless, for very large $N$ these coefficients become perturbative.

6. Vectorlike quarks and leptons

So far we have shown how a Dirac fermion is produced by the binding of a scalar $N$-tuple $\phi$ to a chiral fermion $N$-tuple $\psi_L$. Let us now see how to use this mechanism to generate vectorlike fermions that carry some $SU(3)_c \times SU(2)_W \times U(1)_Y$ gauge charges, as required in various extensions of the SM. If there is a single $\psi_L$, then the gauge anomaly cancellations are not consistent with it carrying hypercharge or transforming in complex representations of $SU(3)_c \times SU(2)_W$. The scalar $\phi$, however, can carry any gauge charges.

A frequently encountered vectorlike fermion [2, 5, 8] transforms as $(3, 1, -1/3)$ under the SM gauge group. This can be a bound state of a $\psi_L$ that is a singlet under the SM group, and a complex scalar $\phi$ that transforms as $(3, 1, -1/3)$. Note that $\psi_L$ can be referred to as a “right-handed neutrino”, while $\phi$ can be identified with a “right-handed squark” of the supersymmetric SM.

If $\psi_L$ is part of a larger set of chiral fermions, each participating together with a scalar $\phi$ in dimension-6 operators of the type [3], there will be a composite vectorlike fermion for each of the elementary chiral fermions. One could imagine applying this set of ideas to the SM model in order to explain the quark and lepton mass hierarchies à la Froggatt-Nielsen [10].

As we alluded earlier, the UV completion responsible for the dimension-6 operator [3] may simply be a heavy gauge boson. If the $SU(N)$ symmetry is gauged and spontaneously broken, the one-gauge-boson exchange between $\psi_L$ and $\phi$ induces operator [3]. Note that the $SU(N)$ symmetry would be anomalous unless additional chiral fermions transform under $SU(N)$. An alternative is that the global $SU(N)$ group is an accidental symmetry arising from a spontaneously-broken gauge group under which $\psi_L$ transforms in a real representation. For example, $\psi_L$ and $\phi$ may belong to the adjoint representation of an $SU(N_0)$ gauge group, with $N_0^2 - 1 = N$. Whether...
the gauge symmetry that provides the binding is $SU(N)$ or $SU(N_0)$, there are bound states in addition to the vector-like fermion, e.g., a $\phi\phi$ composite scalar, that remain to be studied.

7. Conclusions

We have shown that a composite Dirac fermion arises as a bound state of a complex scalar and a chiral fermion, both belonging to the $N$ representation of a global $SU(N)$ group. The binding is provided by an attractive dimension-6 interaction. The origin of this non-confining interaction could be an asymptotically-free gauge group or perhaps within some underlying strongly-coupled theory.

Vectorlike fermions are deployed in a number of models in the literature. Many of these models could be adapted along the present lines to engineer vectorlike fermions as composites. For example, it is not hard to imagine composite Higgs models [3, 4] based on the Top-seesaw mechanism [2] in which the $\chi_L$ and $\chi_R$ top partners arise as composite states as described here.
