Abstract: Interleukin-4 (IL-4) and interleukin-10 (IL-10) are key cytokines whose increased production during systemic HIV infection has been associated with decreased cellular immunity during AIDS. We examined whether HIV-induced stimulation of IL-4 or IL-10 production leads to increased susceptibility to AIDS-related human cytomegalovirus retinitis. It was confirmed that there were increased amounts of IL-4 and IL-10 mRNA levels in mice with MAIDS of 10 weeks duration when most susceptible to MCMV retinitis. Surprisingly, however, MCMV-infected eyes of IL-4 −/− and IL-10 −/− mice with MAIDS of 8 weeks duration exhibited retinitis and infectious virus equivalent to that observed in MCMV-infected eyes of wild-type mice with MAIDS. We conclude that neither IL-4 nor IL-10 alone play a role in increased susceptibility to MAIDS-related MCMV retinitis, but may work collectively with other retrovirus-induced immunosuppressive factors to allow for retinal disease.

Introduction

The immune response is tightly regulated by different CD4+ T-helper cell subsets. Mosmann and coworkers\textsuperscript{1,2} initially demonstrated that T-cell clones exhibit at least one of two distinct cytokine production profiles, including CD4+ T-helper type 1 (Th1) cells that produce Th1 cytokines such as interleukin-2 (IL-2) and interferon-\(\gamma\) (IFN-\(\gamma\)), and CD4+ T-helper type 2 (Th2) cells that produce Th2 cytokines such as IL-4, IL-6, and IL-10.\textsuperscript{2,3} In general, cytokines produced by Th1 cells stimulate macrophage and CD8+ T-cell activation, thereby promoting a response biased toward traditional cell-mediated immunity.\textsuperscript{2,4} In sharp contrast, cytokines produced by Th2 cells activate eosinophils and helper T-cell function for immunoglobulin 1 (IgG1) and immunoglobulin E (IgE) antibody production, thereby promoting a response biased toward traditional humoral immunity and suppression of cellular immunity.\textsuperscript{2,4} While the forces that determine the dominance of Th1 versus Th2 cells are not completely understood, it is clear that Th1 cells predominate in immunologically normal persons.\textsuperscript{3} During HIV infection, however, and the ensuing immune dysregulation that results during progression of AIDS, a unique shift takes place whereby a Th2 response ultimately predominates over a Th1 response.\textsuperscript{5} Thus, cellular immunity is greatly diminished and eventually lost during HIV-induced immunosuppression. In addition, during AIDS there is increased predisposition to a wide spectrum of opportunistic diseases including a sight-threatening retinitis caused by human cytomegalovirus (HCMV).\textsuperscript{6,7}

AIDS-related HCMV retinitis presents clinically as a slowly progressive retinal disease characterized by full-thickness retinal necrosis that is associated with cytomegalic cells.\textsuperscript{6} While use of antiretroviral drugs (ARV) has significantly reduced the number of new cases of AIDS-related HCMV retinitis in the United States,\textsuperscript{8} its incidence in the HIV/AIDS populations of other countries remains high, largely due to the relative unavailability of ARV. For example, a conservative estimate of the incidence of AIDS-related HCMV retinitis in the HIV/AIDS populations of Thailand and Africa remains 33% and 20%, respectively.\textsuperscript{9–11} Thus, vision loss and blindness due to AIDS-related HCMV retinitis remains a major ophthalmologic challenge worldwide.

IL-4 and IL-10 are key Th2 cytokines whose production is stimulated systemically during AIDS (and therefore during AIDS-related HCMV retinitis) as a result of HIV-induced Th2 dominance. IL-4 is an immunomodulatory Th2 cytokine that promotes a number of diverse immunological functions through binding to its two-chain receptor (IL4R) that is expressed on both immune and non-immune cells.\textsuperscript{12,13} Although the immunological outcome(s) of IL-4 secretion varies remarkably depending on effector cell, target cell, and the microenvironment in which IL-4 is secreted,\textsuperscript{12,14,15} IL-4 promotes a number of diverse immunological functions that impact macrophage differentiation, the differentiation of CD4+ T cells into Th2 cells, and the inhibition of secretion of various inflammatory cytokines.\textsuperscript{3} In comparison, IL-10 is an anti-inflammatory Th2 cytokine that inhibits the production of INF-\(\gamma\) as well as other Th1 cytokines,\textsuperscript{3,16} an accomplishment achieved through binding of IL-10 to its two-chain receptor composed of an alpha and beta subunit.\textsuperscript{16,17}

Of greater significance, however, are observations that CD8+ T-cell-mediated cytotoxicity is remarkably diminished at times of increased IL-4 and/or IL-10 production. For example, increased IL-4 production during HIV infection results in conversion of cytotoxic CD8+ T cells to CD8- T cells that also produce more IL-4, further suppressing the Th1 response.\textsuperscript{12,18,19} HIV infection also results in IL-10-producing CD8+ T cells that exhibit reduced cytolytic activity to HIV as well as other viruses including HCMV.\textsuperscript{20} Overexpression of IL-4 in mice also results in increased Fas ligand (FasL) expression on T cells and a concomitant decrease in perforin production, an important observation that suggests that IL-4 favors Fas/FasL-mediated cytotoxicity over perforin-mediated cytotoxicity.\textsuperscript{21} Similar results have also been observed during overexpression of IL-10.\textsuperscript{22,23} Taken together, these findings suggest a pivotal association between increased IL-4 and/or IL-10 production during retrovirus-induced immunosuppression and suppressed cellular immunity, especially cellular immunity involving perforin-mediated cytotoxicity.

We have been investigating the immunological aspects of the pathogenesis of AIDS-related HCMV retinitis using a well-characterized experimental mouse model of murine cytomegalovirus (MCMV) retinitis that develops in C57BL/6 mice with MAIDS,\textsuperscript{6} a murine retrovirus-induced immunodeficiency syndrome that remarkably mimics HIV-induced AIDS.
in humans. Importantly, like patients with AIDS, mice with MAIDS undergo a profound shift in cytokine production by CD4+ T-helper cells from a Th1 dominant phenotype to a Th2 dominant phenotype that commences 3 to 4 weeks after retrovirus infection. This critical immunological event during MAIDS leads to a progressive immunodeficiency characterized by abnormal CD8+ T-cell responses ~8 weeks after retrovirus infection, that ultimately results in high susceptibility to several opportunistic diseases including MCMV retinitis. It is noteworthy that MAIDS-related MCMV retinal disease presents with histopathologic features at 8 to 10 days after MCMV infection that closely resemble those observed in AIDS-related HCMV retinitis, ie, development of a full-thickness retinal necrosis with cytomegalic cells that replaces the normal retinal architecture.

Using our MAIDS model of MCMV retinitis, we demonstrated previously that loss of the perforin cytotoxic pathway is responsible for increased susceptibility to MCMV retinitis during MAIDS, and this increased susceptibility can be reversed by immunotherapy with the Th1 cytokine IL-2. Moreover, MCMV-infected eyes of MAIDS animals susceptible to MCMV retinitis contain high amounts of IL-4. These observations, coupled with those from other laboratories showing that either IL-4 or IL-10 favor the Fas/FasL cytotoxic pathway over the perforin cytotoxic pathway, lead to the attractive hypothesis that an increase in systemic production of IL-4 or IL-10 during retrovirus-induced immunosuppression is responsible for increased susceptibility to MCMV retinitis during MAIDS. To our surprise, however, this hypothesis proved to be incorrect since mice with MAIDS deficient in either IL-4 or IL-10 exhibited a frequency of retinitis, a severity of retinitis, and intraocular amounts of infectious virus equivalent to those found in wild-type mice with MAIDS.

**Methods and Materials**

**Animals**

Wild-type female C57BL/6 mice, IL-4 −/− female mice on a C57BL/6 background, and IL-10 −/− female mice on a C57BL/6 background were purchased from Jackson Laboratories (Bar Harbor, ME). Mice were housed in pathogen-free conditions, allowed unlimited access to food and water, and maintained in alternating 12-hour light/dark cycles. All animal procedures were conducted in accordance with Georgia State University Institutional Animal Care and Use Committee (IACUC) policies as well as the ARVO Statement for Use of Animals in Ophthalmic and Vision Research.

**Viruses**

Stocks of MCMV (Smith strain, American Type Culture Collection, Manassas, VA) and the murine retrovirus mixture (LP-BM5) (kindly provided by the AIDS Research and Reference Reagent Program, Germantown, MD) were prepared and stored as previously described.

**Induction of MAIDS**

MAIDS was induced in 3-week-old wild-type mice, IL-4 −/− mice, and IL-10 −/− mice with the LP-BM5 retrovirus mixture by intraperitoneal injection as described previously. MAIDS-4, 8-weeks duration (MAIDS-8), and 10-weeks duration (MAIDS-10) were used throughout the investigation.

**Subretinal inoculation with MCMV**

Eyes of wild-type MAIDS-8 mice, IL-4 −/− MAIDS-8 mice, and IL-10 −/− MAIDS-8 mice were inoculated with MCMV as described previously. Briefly, 2 µL of maintenance medium containing approximately 10⁴ to 10⁵ plaque-forming units (PFU) of MCMV was injected subretinally into the left eye of each mouse. The right eye of each mouse was injected subretinally with 2 µL of maintenance medium only and served as control for all investigations.

**Quantitative real-time RT-PCR assay**

Total ribonucleic acid (RNA) was extracted from whole splenic cells and from whole eyes using Trizol (Invitrogen, Grand Island, NY) coupled with the PureLink Micro-to-Midi Total RNA Purification System (Invitrogen, Grand Island, NY) following manufacturer’s instructions. Extracted total RNA was stored at −80 °C prior to processing. Extracted total RNA was subjected to reverse transcription following the SuperScript III First-Strand System for RT-PCR (Invitrogen) protocol. Complimentary DNA (cDNA) was stored at −20 °C prior to processing. cDNA from whole splenic cells and whole eyes from all animals was subjected to quantitative real-time RT-PCR to determine the amount of transcripts.
specific for murine IL-4, murine IL-10, murine perforin, murine granzyme B, and murine FasL (Qiagen, Valencia, CA). Murine GAPDH cDNA (Qiagen) served as endogenous control. Briefly, 1.2 µL of cDNA was added to a reaction mixture of 15 µL of Power SYBR Green Master Mix (Applied Biosystems, Carlsbad, CA), 3 µL of primers for each gene (see Table 1), 9.9 µL of double-distilled water, and 0.9 µL of dimethylsulfoxide (Sigma, St. Louis, MO) for a total volume of 30 µL per reaction. Parameters for each quantitative RT-PCR assay cycle were 15 minutes at 95 °C, 15 seconds at 94 °C, 31 seconds at 55 °C, and 35 seconds at 72 °C for a total of 45 cycles. Transcription levels were determined utilizing the 7500 Fast Real-Time PCR System (Applied Biosystems), and average threshold cycles (Ct) were determined using the 7500 Fast Real-Time PCR System software (Applied Biosystems).

ELISA
Whole splenic cells and whole eyes from all animals were collected, individually stored in liquid nitrogen, thawed, individually homogenized in 1.0 mL of phosphate-buffered saline (PBS) containing a protease inhibitor cocktail (Sigma), and individually stored at −20 °C prior to performance of ELISA. At time of ELISA, homogenates were thawed, sonicated, clarified by centrifugation, and the resulting supernatants were subjected to ELISA for quantification of murine IL-4 and IL-10 protein using the commercially available kit provided by eBioscience (San Diego, CA) according to manufacturer’s instructions. Total protein for each sample was determined using the Bradford Protein Assay (Biorad, Hercules, CA).

Histopathology
Whole eyes collected from all animals were immediately fixed in 10% buffered formalin (Electron Microscopy Sciences, Hartford, PA) for at least 48 hours at 4 °C, frozen in Optimal Cutting Temperature (OCT) medium (Thermo Scientific, Rochester, NY), cut into 8-µm sections using a Shandon Special Motorized Electronic Cryotome (Thermo Scientific), and sections were collected onto positively charged microscope slides (Thermo Scientific). Hematoxylin and eosin staining was performed as previously described with minor modifications. Ocular sections were scored for frequency and severity of retinitis using a scoring system established by us previously.

Recovery and quantification of infectious MCMV
Whole MCMV-infected eyes were collected from wild-type MAIDS-8 mice, IL-4 −/− MAIDS-8 mice, and IL-10 −/− MAIDS mice at 10 days after subretinal injection and individually stored in liquid nitrogen prior to processing. At time of quantitative plaque assay, individual eyes were thawed, individually homogenized on ice in 1.0 mL of cold Delbecco’s Minimal Essential Medium (DMEM) (Cellgro, Manassas, VA), and clarified by centrifugation. Ten-fold dilutions of the resulting supernatants were titered onto monolayers of mouse embryo fibroblast (MEF) cells in 6-well plates, allowed to adsorb for 1 hour at 37 °C in a humidified atmosphere of 5% CO₂, overlaid with 1.0 mL DMEM, and incubated for 5 days at 37 °C in a humidified atmosphere of 5% CO₂. Individual plaques were counted using an

inverted light microscope, and results were expressed as the number of PFU per mL per whole eye (PFU/mL/eye).

**Statistical analysis**

All quantitative data obtained from quantitative real-time RT-PCR assay and ELISA were expressed as means ± standard error of the mean (SEM) and standard deviation (SD), respectively. At least two independent experiments per performed for each study. Statistical analysis was performed using the Wilcoxon-rank sum or Student t-test. A P value of <0.05 was considered significant.

**Results**

Quantification of splenic IL-4 and IL-10 messenger RNA levels in wild-type C57BL/6 mice during progression of MAIDS

Early work by Gazzinelli and colleagues demonstrated that progression of MAIDS is associated with a shift in cytokine production by splenic CD4+ T cells from a Th1 profile to a Th2 profile as seen in HIV-infected patients with AIDS, and this shift commences at ∼3 weeks after retrovirus infection. We have shown previously that IL-4 messenger RNA (mRNA) levels increase significantly within the ocular compartment of MCMV-infected eyes of mice with MAIDS. Here, we sought to confirm that in the absence of MCMV infection our animals also exhibit a systemic increase in Th2 cytokines during the progression of MAIDS, especially for the Th2 cytokines IL-4 and IL-10 that have been associated with dampening of cellular immunity. Initial experiments using quantitative RT-PCR assay were therefore performed to measure IL-4 and IL-10 mRNA levels within splenic cells collected from wild-type C57BL/6 mice with MAIDS of 4-weeks duration (MAIDS-4), 8-weeks duration (MAIDS-8), and 10-weeks duration (MAIDS-10), but without ocular MCMV infection. Results are shown in Figure 1. Whereas splenic IL-4 mRNA levels increased nearly 2-fold in MAIDS-4 and MAIDS-8 animals, MAIDS-10 animals showed a significant 4-fold increase in splenic IL-4 mRNA levels (Fig. 1A). In comparison, splenic IL-10 mRNA levels also increased during progression of MAIDS, but this increase was evident later in the course of MAIDS and far greater than that seen for splenic IL-4 mRNA. Whereas no significant increase in IL-10 mRNA was observed in splenic cells collected from MAIDS-4 animals, splenic IL-10 mRNA levels were ∼4-fold and ∼17-fold higher in MAIDS-8 and MAIDS-10 animals, respectively (Fig. 1B). Thus, as expected, our mice with MAIDS did indeed exhibit increased systemic

![Figure 1](https://example.com/figure1.png)

**Figure 1.** IL-4 and IL-10 mRNA levels in whole splenic cells during progression of MAIDS (A) IL-4 mRNA levels in whole splenic cells during MAIDS progression versus healthy controls, P < 0.05 (n = 5), Error bars = Standard Error of Mean (SEM) of three independent experiments. Asterisks indicate statistical significance. (B) IL-10 mRNA levels in whole splenic cells during MAIDS progression versus healthy controls, P < 0.03 (n = 5), error bars = SEM of two independent experiments.
production of IL-4 and IL-10 mRNAs during progression of retrovirus-induced immunosuppression as measured using splenic cells, although the increase in splenic IL-10 mRNA levels was far greater than that of splenic IL-4 mRNA levels. Nonetheless, a significant increase in systemic mRNA levels to both Th2 cytokines was observed during MAIDS-8 and MAIDS-10, times during the course of retrovirus-induced immunosuppression when mice become susceptible to MCMV retinitis following subretinal infection.26,32

Induction of MAIDS in mice deficient in IL-4 or IL-10

To determine if systemic reduction of IL-4 or IL-10 might lead to increased resistance to MCMV retinitis during MAIDS as hypothesized, we first attempted to induce MAIDS in IL-4−/− mice and IL-10−/− mice. Since IL-4 and IL-10 gene-deficient mice are not available, we elected to use IL-4−/− and IL-10−/− mice for these studies that possess a targeted mutation of the IL-4 gene or IL-10 gene. This mutation results in the production of truncated, non-functional IL-435 or IL-1036 protein products. Groups of IL-4−/− and IL-10−/− mice were therefore infected with the immunosuppressive retrovirus mixture LP-BM5, housed for 8 weeks, and assessed for development of MAIDS using criteria established by us previously.32 All retrovirus-infected IL-4−/− and IL-10−/− mice exhibited physical and immunological features consistent with development of MAIDS (data not shown), and were designated as IL-4−/− MAIDS-8 mice and IL-10−/− MAIDS-8 mice.

Additional studies were performed to confirm that splenic IL-10 mRNA levels were not affected in IL-4−/− MAIDS-8 mice following subretinal MCMV infection. Conversely, splenic IL-4 mRNA levels were not affected in IL-10−/− MAIDS-8 mice following subretinal MCMV infection. This finding was of interest since Green and coworkers37 noted that IL-10−/− mice infected with LP-BM5 exhibited exaggerated disease development when compared with wild-type LP-BM5-infected C57BL/6 mice, an outcome that might affect splenic IL-4 mRNA production. Results are shown in Figure 2. While equivalent amounts of IL-10 mRNA levels were observed in splenic cells collected from wild-type MAIDS-8 mice and IL-4−/− MAIDS-8 mice following intraocular MCMV infection, IL-10 protein levels were significantly increased in IL-4−/− MAIDS-8 mice. In comparison, while splenic IL-4 mRNA levels were reduced by ∼50% in IL-10−/− MAIDS-8 mice when compared with wild-type MAIDS WT MAIDS IL-4−/− MAIDS WT MAIDS IL-10−/−

Figure 2. IL-10 mRNA and IL-10 protein levels in whole splenic cells of IL-4−/− MAIDS-8 mice versus respective controls and IL-4 mRNA and IL-4 protein levels in whole splenic cells of IL-10−/− MAIDS-8 mice versus respective controls. (A) IL-10 mRNA levels in whole splenic cells of wild-type MAIDS versus IL-4−/− MAIDS-8 mice, P = 0.432 (n = 10). Error bars = SEM of two independent experiments. (B) IL-10 protein levels in whole splenic cells of wild-type MAIDS versus IL-4−/− MAIDS-8 mice, P ≤ 0.02 (n = 10), error bars = Standard Deviation (SD) of two independent experiments. Asterisks indicate statistical significance. (C) IL-4 mRNA in whole splenic cells of wild-type MAIDS versus IL-10−/− MAIDS-8 mice, P ≤ 0.04 (n = 5), error bars = SEM of one experiment. Asterisks indicate statistical significance. (D) IL-4 protein in whole splenic cells of wild-type MAIDS versus IL-10−/− MAIDS-8 mice, P = 0.939 (n = 8, wild-type MAIDS-8 mice; n = 10, IL-10−/− MAIDS-8 mice), error bars = SD of one experiment.
MAIDS-8 mice following intraocular MCMV infection, nearly equivalent amounts of IL-4 protein were found within splenic cells of both animal groups.

Quantification of amounts of infectious MCMV within eyes of wild-type MAIDS-8 mice, IL-4 −/− MAIDS-8 mice, and IL-10 −/− MAIDS-8 mice following subretinal MCMV infection

We have shown previously that the amounts of infectious MCMV within the ocular compartments of mice with MAIDS increase remarkably during development of retinitis following subretinal MCMV injection.6,26,32 Moreover, since increased IL-4 and IL-10 production would tend to delay virus clearance by dampening of CD8+ T-cell cytotoxicity, we sought to determine if loss of IL-4 or IL-10 would affect virus replication during MAIDS. Eyes of IL-4 −/− MAIDS-8 mice, IL-10 −/− MAIDS-8 mice, and wild-type MAIDS mice were therefore infected with MCMV by subretinal injection, collected 10 days later, and subjected to standard plaque assay for quantification and comparison of amounts of infectious virus. As shown in Figure 3, equivalent amounts of infectious virus were found in MCMV-infected eyes of IL-4 −/− MAIDS-8 mice, IL-10 −/− MAIDS-8 mice, and their respective wild-type MAIDS-8 controls. Thus, systemic loss of IL-4 or IL-10 during MAIDS did not appear to impact virus replication significantly within the eye, either positively or negatively.

Frequency and severity of MCMV retinitis in IL-4 −/− MAIDS-8 mice and IL-10 −/− MAIDS-8 mice following subretinal MCMV infection

Since systemic loss of IL-4 or IL-10 had no effect of the amount of virus within the eyes of MAIDS-8 mice that have been shown previously by us to be susceptible to retinitis,6,32 we sought to determine whether systemic loss of IL-4 or IL-10 would result in increased resistance to retinitis as hypothesized. In separate experiments, IL-4 −/− MAIDS-8 mice, IL-10 −/− MAIDS-8 mice, and their respective wild-type MAIDS-8 controls were infected with MCMV by subretinal inoculation. Ten days later, all eyes were collected, analyzed histopathologically, and scored for frequency and severity of necrotizing retinitis using a scoring system described previously.32 Results are shown in Table 2. As expected, MCMV-infected eyes of wild-type MAIDS-8 control mice were indeed susceptible to retinitis as indicated by frequencies of retinitis of 78% and 100% in separate experiments (average = 89%). In sharp opposition to our hypothesis, however, MCMV-infected eyes collected from IL-4 −/− MAIDS-8 mice and IL-10 −/− MAIDS-8 mice exhibited a frequency of retinitis equivalent to that observed in control animals. Whereas 89% of MCMV-infected eyes of IL-4 −/− MAIDS-8 mice showed retinitis, 85% of IL-10 −/− MAIDS-8 mice also showed retinitis.
Although frequency of retinitis was unaffected in MAIDS animals with a systemic loss of IL-4 or IL-10, it was possible that loss of these Th2 cytokines would result in a decrease in severity of retinal disease. This was not the case (Table 2). When scored for severity of retinitis, no statistical difference was observed when MCMV-infected eyes of IL-4−/− MAIDS-8 mice or MCMV-infected eyes of IL-10−/− MAIDS-8 mice were compared with MCMV-infected eyes of their respective controls.

Quantification of splenic perforin, granzyme B, and FasL mRNA levels in IL-4−/− MAIDS-8 mice and IL-10−/− MAIDS-8 mice following subretinal MCMV infection

Since MCMV-infected eyes of mice with MAIDS deficient in systemic IL-4 or IL-10 failed to show a decrease in frequency or severity of retinitis as predicted, we were interested in knowing the fate of mRNAs of key molecules involved in CD8+ T-cell cytotoxicity in animals unable to produce functional systemic IL-4 or IL-10. These included perforin and granzyme B mRNAs associated with the perforin cytotoxic pathway and FasL mRNA associated with the Fas/FasL cytotoxic pathway. This finding...
was accomplished by measurement of perforin, granzyme B, and FasL mRNAs originating from splenic cells collected from IL-4−/− MAIDS-8 mice and IL-10−/− MAIDS-8 mice following subretinal MCMV infection, and comparing these amounts by quantitative RT-PCR assay with those obtained from wild-type MAIDS-8 mice following subretinal MCMV infection. As shown in Figure 4, amounts of splenic perforin and granzyme B mRNAs remained relatively unchanged in mice with MAIDS deficient in systemic IL-4 or IL-10 production when compared with wild-type MAIDS animals. Moreover, MAIDS mice deficient in systemic IL-4 or IL-10 production showed a significant increase in splenic FasL mRNA production, which was an unexpected finding.

Discussion
Since its appearance as a major cause of vision loss and blindness within the United States nearly 30 years ago, AIDS-related HCMV retinitis has become well characterized clinically and histologically.6,38 Despite many years of extensive clinical and laboratory investigation, however, a number of basic issues related to the virology, immunology, and pathogenesis of this sight-threatening disease within the unique immunosuppressive environment of HIV infection and disease remain unresolved. Among these unresolved issues is the lack of a crisp and comprehensive understanding of the basic immunological changes that take place during retrovirus-induced immunosuppression, especially those involved during loss of cellular immunity. Toward this end, we previously used our MAIDS model of MCMV retinitis to show that the perforin-mediated cytotoxic pathway is more important than the Fas/FasL-mediated cytotoxic pathway for protection against MAIDS-related MCMV retinitis.24 We24 and others39 showed that loss of the perforin cytotoxic pathway results in an increased susceptibility to MCMV-induced disease, including retinitis. Resistance to MCMV-related disease, however, could be restored by immunotherapy with the Th1 cytokine IL-2,25 a cytokine that has robust effects on cytotoxic T cell and natural killer (NK) cell functions.40 Unanswered in these investigations, however, was an understanding of the precise mechanism(s) by which the perforin cytotoxic pathway is diminished during MAIDS in favor of the Fas/FasL cytotoxic pathway. These findings, coupled with the fact that progression of MAIDS is also associated with a prominent shift in cytokine production by CD4+ T cells from a Th1 profile to a Th2 profile6 (Fig. 1) as seen during AIDS,5 lead to the attractive hypothesis that IL-4 or IL-10, both Th2 cytokines that have been shown to be involved in downregulation of cellular immunity,21,24,27,28,31 play key roles in the pathogenesis of MAIDS-related MCMV retinitis.

Surprisingly, results reported herein suggest that this is not the case, and our hypothesis is incorrect. In fact, MCMV-infected eyes of mice with MAIDS deficient in systemic IL-4 or IL-10 displayed a frequency of retinitis, a severity of retinitis, and intraocular amounts of virus equivalent to those found in MCMV-infected eyes of wild-type mice with MAIDS.

That IL-4 or IL-10 should play a pivotal role in loss of cellular immunity during the pathogenesis of MAIDS-related MCMV retinitis was a reasonable prediction. In addition to studies showing that increased IL-4 or IL-10 production during HIV infection results in decreased cytotoxic CD8+ T-cell activity against many viruses including HCMV,18–20,41 numerous in vitro and in vivo studies have also noted an association between elevated levels of the Th2 cytokine IL-4 and decreased CD8+ T-cell-mediated cytotoxicity, all associated with an increase in FasL expression and a concomitant decrease in perforin and granzyme B expression. For example, Kienzle and colleagues27,28 demonstrated that incubation of naïve mouse CD8+ T cells with high concentrations of IL-4 resulted in a population of T cells with significantly lower expression of CD8 and reduced cytotoxic ability. Aung and coworkers21 infected mice with an IL-4-expressing respiratory syncytial virus (RSV) recombinant and observed a subsequent increase in expression of FasL on CD4+ and CD8+ T cells coupled with alteration of the mechanism of CD8+ T-cell cytotoxicity from a perforin-mediated pathway to a favored Fas/FasL-mediated pathway. Moreover, systemic treatment of mice with anti-IL-4 antibody resulted in decreased morbidity following challenge with wild-type RSV due to an enhanced CD8+ cytotoxic response that lead to more effective virus clearance.21 Similar findings were reported by Jackson and colleagues45 for mousepox virus infection. These workers observed suppressed CD8+ T-cell cytotoxicity as well as suppressed NK-cell cytotoxicity in mice infected with an IL-4-expressing mousepox virus, outcomes that resulted in increased virus-induced mortality.

Ophthalmology and Eye Diseases 2012:4
Despite this convincing body of evidence, we did not observe increased resistance to MCMV retinitis in mice with MAIDS in the absence of functional IL-4 or IL-10 production as hypothesized. Without functional IL-4 or IL-10, two Th2 cytokines thought to dampen cellular immunity during retrovirus-induced immunosuppression,\cite{18,20,23,41} we predicted a resurgence in CD8+ T-cell cytotoxicity that would provide protection against onset and progression of MCMV-induced retinal disease, possibly through stimulation of the perforin cytotoxic pathway associated with a concomitant decline in the Fas/FasL cytotoxic pathway. Surprisingly, this was not the case. In fact, loss of IL-4 or IL-10 during MAIDS resulted in no significant change in splenic mRNA levels for perforin or granzyme B, two key molecules involved in the perforin cytotoxic pathway, when compared with wild-type mice with MAIDS. More importantly, an increase in splenic mRNA levels for FasL was observed following loss of either IL-4 or IL-10 during MAIDS when compared with wild-type mice with MAIDS. One explanation for these unexpected results is that while IL-4 or IL-10 may work individually to suppress cellular immunity during MAIDS, they also function collectively toward this end. Our findings suggest that loss of IL-4 or IL-10 during MAIDS is an independent event that fails to affect production of the other Th2 cytokine. Thus, loss of one of these Th2 cytokines does not necessarily lead to a significant biological outcome as measured in our studies by a change in frequency or severity of MAIDS-related MCMV retinitis. One experimental approach to test this hypothesis would be to perform parallel studies using mice with MAIDS that suffer systemic loss in both IL-4 and IL-10 production. Unfortunately, all commercially available double knockout mice at present exist only on a BALB/c background, and MAIDS cannot be induced in BALB/c mice.\cite{43} Alternatively, we could reduce systemic levels of both IL-4 and IL-10 in mice with MAIDS using an antibody approach to neutralize their functions, but pilot studies to reduce systemic levels of IL-4 alone in mice with MAIDS using anti-IL-4 antibody have proven to be ineffective, resulting in only ∼50% reduction in splenic levels of IL-4 mRNA and protein (data not shown). Thus, future studies will be oriented toward production of IL-4 and IL-10 double knockout mice on a C57BL/6 background to explore the exciting possibility that these Th2 cytokines act in concert to increase susceptibility to MCMV retinitis during MAIDS.

It is noteworthy, however, that more recent findings from other laboratories have suggested that IL-4 can indeed support development of cytotoxic T cells when incubated with highly purified primary T cells collected from lymph nodes of BALB/c mice.\cite{44,45} Studies conducted by Bachmann and coworkers\cite{46} also demonstrated that IL-4−/− C57BL/6 mice, when compared with wild-type C57BL/6 mice, failed to exhibit changes in cytotoxic T-cell responses when infected with lymphocytic choriomeningitis virus or vaccinia virus. These animals were also able to clear virus as a result of an effective cytotoxic T-cell response. Additional studies conducted by Mo and colleagues\cite{17} noted that CD8+ T cells collected from IL-4−/− 129/J mice and wild-type 129/J mice exhibited equivalent cytotoxic activity against Sendai virus infection. It is important to recognize, however, that none of these studies investigated IL-4 and cellular immunity in the context of retrovirus-induced immunosuppression.

In summary, we show herein that mice with MAIDS deficient in either IL-4 or IL-10 do not develop resistance to MCMV retinitis as measured by amounts of intraocular infectious virus, frequency of retinitis, and severity of retinitis. Our findings therefore disprove our initial working hypothesis that IL-4 or IL-10 are key Th2 cytokines that promote increased susceptibility to MAIDS-related MCMV retinitis by dampening cellular immunity, possibly because they favor the Fas/FasL cytotoxic pathway over the perforin cytotoxic pathway. In hindsight, this was probably a naïve hypothesis since IL-4, IL-10, and many other host factors probably work in concert during MAIDS to create the unique intraocular environment that allows for pathogenesis of MCMV retinitis. Our present studies are oriented toward precise identification of these unique factors.
