College of Physical Sciences, Graduate University of Chinese Academy of Sciences, P. O. Box 4588, Beijing 100049, People’s Republic of China

The magnetic and thermodynamic properties of a new ferrimagnetic decorated spin-(1/2, 1) Heisenberg chain with spin-1 pendant spins are investigated for three cases: (A) J1, J2>0; (B) J1>0, J2<0; and (C) J1<0, J2>0, where J1 and J2 are the exchange couplings between spins in the chain and along the rung, respectively. The low-lying and magnetic properties are explored jointly by the real-space renormalization group, spin wave, and density-matrix renormalization group methods, while the transfer-matrix renormalization group method is invoked to study the thermodynamics. It is found that the magnon spectra consist of a gapless and two gapped branches. Two branches in case (C) have intersections. The coupling dependence of low-energy gaps are analyzed. In a magnetic field, a m=3/2 (m is the magnetization per unit cell) plateau is observed for case (A), while two plateaux at m=1 and 3 are observed for cases (B) and (C). Between the two plateaux in cases (B) and (C), the sublattice magnetizations for the spins coupled by ferromagnetic interactions have novel decreasing regions with increasing the magnetic field. At finite temperature, the zero-field susceptibility temperature product χT and specific heat exhibit distinct exotic features with varying the couplings and temperature for different cases. χT is found to converge as T→0, which is different from the divergent behavior in the spin-(1/2, 1) mixed-spin chain without pendants. The observed thermodynamic behaviors are also discussed with the help of their low-lying excitations.

I. INTRODUCTION

In recent years, one-dimensional (1D) quantum ferrimagnets with two kinds of antiferromagnetically exchange-coupled centers have attracted much attention due to their exotic properties. The large families of compounds ACu(pba)(H2O)3·nH2O and ACu(pbaOH)(H2O)3·nH2O, where A=Mn, Fe, Co, Ni, Zn, pba=1,3-propylenebis, and pbaOH=2-hydroxy-1,3-propylenebis, have been extensively explored in chemistry which are good realizations of the mixed-spin chains. These compounds exhibit typically the 1D ferrimagnetic behavior of χT (χ is the magnetic susceptibility and T is the temperature) that shows a rounded minimum with temperature.

As a simple model to describe the mixed-spin chains, the antiferromagnetically coupled spin-(1/2, 1) Heisenberg chain have also been extensively studied by various methods, such as the spin wave theory quantum Monte Carlo and so on. It has been found that its ground state has a spontaneous magnetization at m=1/2 (m is the magnetization per unit cell) that is consistent with the Lieb-Mattis theorem and the system has a ferrimagnetic (FI) long-range order. The one-magnon excitation spectra consist of a gapless ferromagnetic (FM) branch from SC to SC−1 (SC is the good quantum number of total spin in z component in the ground state) and a gapped antiferromagnetic (AFM) branch from SC to SC+1. This magnon gap was numerically found to be 1.759J (J is the exchange coupling). In a magnetic field, the system exhibits a magnetization plateau at m=1/2 with the width of 1.759J, corresponding to the gap of the AFM magnon branch. Different from the S=1 Haldane chain, in this mixed-spin chain the spin gap (1.2795J) from the ground state to the lowest state in the subspace of SG + 1 is less than the magnon gap (1.759J) and thus is not a magnon-like excitation. The thermodynamic properties in the coexistence of the AFM and FM excitations and in the critical phase under a magnetic field have also been investigated.

Recently, another interesting family of cyanide-bridged coordination compounds with pendant magnetic ions are synthesized in experiment. One of them is the cyanide-bridged Ni(II)-Fe(III) complex with a novel building block [Fe(1-CH3im)(CN)5]2− which can be treated as the 1D structure as shown schematically in Fig. 1 owing to the weak interchain interactions, where the Ni(II) (Si and ri) and Fe(III) (τi) ions have spin 1 and 1/2, respectively. This compound realizes a decorated spin-(1/2, 1) mixed-spin chain with spin-1 pendant spins. Although the intrachain couplings J1<0 and J2<0 are both FM interactions in the present compound, it is noticed that any other couplings (i.e., J1, J2>0, J1>0 and J2<0, J1<0 and J2>0) would give rise to ferrimagnets, making the realization of such a FI structure more ac-

FIG. 1: (Color online) Sketch of the spin-(τ, S) decorated Heisenberg chain with spin-σ pendant spins.
cessible to the experiment. This family of mixed-spin chains with pendant spins provides a new scheme to study the 1D quantum ferrimagnetism, which may have new exotic properties. Although the influences of pendant spins on magnetism have been discussed in some antiferromagnets, the studies on such ferrimagnets are still rare till now.

In this paper, we shall explore the physical properties of this new ferrimagnetic structure, and compare with the spin-(\(\frac{1}{2},1\)) mixed-spin chain without pendants. The low-lying, magnetic and thermodynamic properties of the spin-(\(\frac{1}{2},1\)) decorated Heisenberg chain with spin-1 pendant spins for three cases: (A) \(J_1, J_2>0\); (B) \(J_1>0, J_2<0\); and (C) \(J_1<0, J_2>0\) will be studied using various techniques. It is unveiled that due to the pendant spins, the new ferrimagnets exhibit rather distinct magnetic and thermodynamic behaviors from those of the spin-(\(\frac{1}{2},1\)) mixed-spin chain. The three cases with different couplings are uncovered to have their own features, which are expected to observe in experiments. The exotic properties of this system will also shed light on further understandings of quantum ferrimagnetism.

This paper is organized as follows. In Sec. II, the model Hamiltonian is introduced. In Sec. III, the low-energy effective Hamiltonians in both strong and weak couplings are analyzed utilizing the real-space renormalization group (RSRG) method. The low-lying excitations and magnetic properties are investigated by the linear spin wave (LSW) theory and DMRG in Sec. IV. In Sec. V, we shall study the zero-field thermodynamics by means of the transfer-matrix renormalization group (TMRG). Finally, a summary and discussion will be given in Sec. VI.

II. MODEL HAMILTONIAN

The Hamiltonian of the spin-(\(\frac{1}{2},1\)) decorated Heisenberg chain with spin-1 pendant spins in a magnetic field can be written as

\[
H = \sum_{i=1}^{N} (J_1 \vec{\sigma}_i \cdot \vec{S}_i + J_1 \vec{S}_i \cdot \vec{\tau}_{i+1} + J_2 \vec{\tau}_i \cdot \vec{\sigma}_i) - \hbar \sum_{i=1}^{N} (\vec{\tau}_i^\tau + \vec{S}_i^z + \vec{\sigma}_i^z),
\]

where \(\vec{\sigma}_i\) is the \(\sigma=1\) pendant spin, \(\vec{\tau}_i\) and \(\vec{S}_i\) are the spins in the chain with \(\tau=\frac{1}{2}\) and \(S=1\), respectively, \(J_{1,2}>0\) (\(<0\)) denote the AFM (FM) couplings, and \(\hbar\) is the magnetic field. Throughout the context, we take \(J_1\) as an energy scale and \(\mu_B=1\). The schematic representation of the model is shown in Fig. 1.

Analogous to the spin-(\(\frac{1}{2},1\)) mixed-spin chain without pendants, the system with Hamiltonian (11) has a spontaneous magnetization in the absence of magnetic field according to the Lieb-Mattis theorem. In case (A) \((J_{1,2}>0)\) the spontaneous magnetization per unit cell is \(m=\frac{1}{4}\), while in both cases (B) \((J_1>0, J_2<0)\) and (C) \((J_1<0, J_2>0)\) it is spontaneously magnetized at \(m=\frac{3}{2}\).

The Goldstone theorem allows gapless excitations in these cases owing to the spontaneous breaking of the SU(2) symmetry.

III. REAL SPACE RENORMALIZATION GROUP ANALYSIS

In this section, the low-energy effective Hamiltonians of the three cases in both strong- and weak-coupling limits are derived utilizing the RSRG. In the RSRG procedure, the Hamiltonian is divided into intrablock (\(H^B\)) and interblock (\(H^{BB}\)) parts. By diagonalizing \(H^B\), a number of low-energy states are kept to project the full Hamiltonian into the renormalized Hilbert space. Although RSRG cannot give the results as accurate as the numerical approaches, it can give a good qualitative description for low-energy properties.

A. \(J_1>0, J_2>0\)

Let us first consider the strong-coupling limit (\(J_2\gg J_1\)). Since the interaction between \(\tau\) and \(\sigma\) is strong, each rung can be considered as the isolated block in the first step of renormalization group (RG). Each block consists of two multiplets whose total spins are 1/2 and 3/2 with energies \(-J_2\) and \(J_2/2\), respectively. The spin-\(\frac{1}{2}\) doubles are kept as the basis to construct the embedding operator \(T\) to project the full Hamiltonian onto the truncated Hilbert space. The effective Hamiltonian can be obtained as

\[
\tilde{H}^{\text{strong},1}_A = -N J_2 - \frac{1}{3} J_1 \sum_{i=1}^{N} (\vec{S}_i' \cdot \vec{S}_i + \vec{S}_i' \cdot \vec{S}'_{i+1}),
\]

where \(S_i'=1/2\) is the renormalized spin truncated from the rung block. The Hamiltonian (2) describes a spin-(\(\frac{1}{2},1\)) mixed-spin chain with a renormalized FM coupling \(-\frac{1}{3}J_1\). In the next step of RG procedure, the Hamiltonian (2) is further projected onto a \(S''=3/2\) FM Heisenberg chain

\[
\tilde{H}^{\text{strong},2}_A = -(J_2 + \frac{J_1}{6}) N - \frac{2}{27} J_1 \sum_{i=1}^{N} S_i'' \cdot S_{i+1}''.
\]

The magnon excitations in this FM Hamiltonian correspond to the magnons from \(S_G\) to \(S_G'\) in the original system, which are hence expected to be gapless with a quadratic dispersion in low energies. The RG can also give the sublattice magnetization \(m_s=1\), \(m_{z}=\frac{3}{2}\), and \(m_{\sigma}=\frac{2}{3}\). The sum of them gives \(\frac{3}{2}\), recovering the spontaneous magnetization of the original system.

In the weak-coupling limit (\(J_2 \ll J_1\)), the spins \(\vec{\tau}_i\) and \(\vec{S}_i\) are taken as a block, and the doubles with spin 1/2 are
kept to truncate the block Hilbert space. The effective Hamiltonian is
\[ \hat{H}_{B}^{\text{weak},1} = -NJ_1 - \sum_{i=1}^{N} \left( \frac{4}{9} J_1 \vec{S}_i \cdot \vec{S}_{i+1} + \frac{1}{3} J_2 \vec{S}_i \cdot \vec{S}_i \right), \]
where \( S_i' = \frac{1}{2} \) is the renormalized block spin. The Hamiltonian is mapped onto a spin-1/2 FM Heisenberg chain with \( \sigma = 1 \) pendants coupled by the renormalized AFM interaction \(-\frac{1}{3} J_2\). The spin wave analysis unveils that it has a gapless FM excitation with the dispersion
\[ \omega_k \sim \frac{2}{27} J_1 k^2 \]
for \( k \to 0 \), which corresponds to the magnon excitation from \( S_G \) to \( S_G - 1 \) of the original system. The sublattice magnetization is obtained as \( m_\sigma = \frac{2}{3}, \ m_\tau = -\frac{1}{6}, \) and \( m_\tau = 1 \), and the sum of them is \( \frac{5}{2} \).

From Eqs. (2) and (3) it can be seen that in the two coupling limits, the low-energy behaviors of the gapless branch are both dominated by \( J_1 \). Besides, \( m_\sigma \) and \( m_\tau \) exchange their values in the two limits, and \( m_\tau \) is unchanged, implying a possible crossing of \( m_\tau \) in the intermediate region of \( J_2 / J_1 \), which would be confirmed by the DMRG results in the next section.

**B. \( J_1 > 0, J_2 < 0 \)**

In the strong-coupling limit (\( |J_2| \gg |J_1| \)), owing to the strong FM \( J_2 \), the low-energy multiplets with total spin 3/2 are kept to project the Hamiltonian in the first step of RG. The effective Hamiltonian is obtained as
\[ \hat{H}_{B}^{\text{strong},1} = \frac{1}{2} J_2 N + \frac{J_1}{3} \sum_{i=1}^{N} (\vec{S}_i \cdot \vec{S}_i + \vec{S}_i \cdot \vec{S}_{i+1}) \]
with the renormalized spin of rung block \( S_i' = 3/2 \), which depicts a spin-(\( \frac{3}{2}, 1 \)) Heisenberg chain with a renormalized AFM coupling \( \frac{J_1}{3} \). In the next step of RG procedure the Hamiltonian \( \hat{H}_{B}^{\text{strong},1} \) is projected to a \( S'' = 1/2 \) FM Heisenberg chain
\[ \hat{H}_{B}^{\text{strong},2} = \frac{1}{6} (3J_2 - 5J_1) N - \frac{10}{27} J_1 \sum_{i=1}^{N} \vec{S}_i \cdot \vec{S}_i, \]
whose FM excitations imply that the magnon excitations of the original system from \( S_G \) to \( S_G - 1 \) are gapless with a quadratic dispersion relation in low energies. The sublattice magnetization is obtained as \( m_\sigma = -\frac{1}{3}, \ m_\tau = \frac{5}{18}, \) and \( m_\tau = \frac{5}{9} \), giving rise to the spontaneous magnetization per unit cell \( m = \frac{5}{9} \).

In the weak-coupling limit (\( |J_2| \ll |J_1| \)), we perform the RG on the block spins \( \vec{S}_i \) and \( \vec{S}_i \) with the doublet of total spin 1/2. The effective Hamiltonian is
\[ \hat{H}_{B}^{\text{weak},1} = -NJ_1 - \frac{4}{9} \sum_{i=1}^{N} (J_1 \vec{S}_i \cdot \vec{S}_{i+1} + \frac{1}{3} J_2 \vec{S}_i \cdot \vec{S}_i) \]
with the renormalized spin \( S_i' = 1/2 \), which describes a spin-1/2 FM Heisenberg chain with \( \sigma = 1 \) pendants coupled by the renormalized AFM interaction \(-\frac{1}{3} J_2\). The spin wave results show that the excitations that correspond to those from \( S_G \) to \( S_G - 1 \) in the original system are also gapless with
\[ \omega_k \sim \frac{2}{9} J_1 k^2 \]
for \( k \to 0 \). In the two limits, it is observed from Eqs. (10) and (11) that the low-energy behaviors of the gapless excitation are both dominated by \( J_1 \).

**C. \( J_1 < 0, J_2 > 0 \)**

For the strong-coupling limit (\( J_2 \gg |J_1| \)), because of the strong AFM \( J_2, \vec{S}_i \) and \( \vec{S}_i \) are renormalized by the doublet with total spin 1/2. The effective Hamiltonian is given by
\[ \hat{H}_{C}^{\text{strong},1} = -NJ_2 - \frac{1}{3} J_1 \sum_{i=1}^{N} (\vec{S}_i \cdot \vec{S}_i + \vec{S}_i \cdot \vec{S}_{i+1}) \]
with \( S' = 1/2 \). Eq. (11) describes a spin-(\( \frac{3}{2}, 1 \)) Heisenberg chain coupled by the renormalized AFM interaction \(-\frac{1}{3} J_1 \) in the second step of RG, the Hamiltonian (11) is projected to a \( S'' = 1/2 \) FM Heisenberg chain
\[ \hat{H}_{C}^{\text{strong},2} = - (J_2 - \frac{J_1}{3}) N + \frac{4}{27} J_1 \sum_{i=1}^{N} \vec{S}_i \cdot \vec{S}_i, \]
which unveils the gapless excitations from \( S_G \) to \( S_G - 1 \) of the original system. The sublattice magnetization is obtained as \( m_\sigma = -\frac{2}{3}, \ m_\tau = \frac{1}{18}, \) and \( m_\sigma = -\frac{2}{3} \), giving rise to the spontaneous magnetization per unit cell \( m = \frac{5}{9} \).

In the weak-coupling limit (\( J_2 \ll |J_1| \)), the spins \( \vec{S}_i \) and \( \vec{S}_i \) are taken as a block, and the multiplet with spin 3/2 are kept to truncate the block Hilbert space. The effective Hamiltonian is obtained as
\[ \hat{H}_{C}^{\text{weak},1} = \frac{1}{2} N J_1 + \sum_{i=1}^{N} \left( \frac{2}{9} J_1 \vec{S}_i \cdot \vec{S}_i + \frac{1}{3} J_2 \vec{S}_i \cdot \vec{S}_i \right), \]
which describes a spin-3/2 FM Heisenberg chain with antiferromagnetically coupled pendant spins \( \vec{S}_i \). The spin wave analysis indicates that the effective system has a FM gapless excitation with
\[ \omega_k \sim -J_1 k^2 \]
for \( k \to 0 \). Analogous to the above cases, the low-energy behavior of the gapless branch in the two limits are determined by \( J_1 \), which can be seen from Eqs. (10) and (11).

Based on the RSRG analyses, one may observe that the different cases have distinct low-energy effective Hamiltonians, and the magnon excitations from \( S_G \) to \( S_G - 1 \).
are always FM and gapless, being consistent with those of the spin-(½, 1) mixed spin chain. The dispersion relations near \(k=0\) are found to be dominated by \(J_1\) in both strong and weak couplings. The low-energy effective Hamiltonians for cases (B) and (C) in the strong-coupling limit are analogous except the magnitude of spin, whose thermodynamic properties will be compared in Sec. V.

IV. LOW-LYING EXCITATIONS AND MAGNETIC PROPERTIES

In this section, the low-lying excitations and magnetic properties are explored by means of the LSW\(^{21,22}\) and DMRG.\(^{21,22}\) During the DMRG calculations, the chain length is taken as \(L=300\), and the Hilbert space is truncated to 240 most relevant states. Open boundary conditions are adopted, and the truncation error is less than \(10^{-8}\) in all calculations.

A. \(J_1>0, J_2>0\)

The Holstein-Primakoff (HP) transformations are introduced as follows:

\[
\sigma_i^+ = s_i - a_i^\dagger a_i, \\
\sigma_i^- = \sqrt{2s_i} - a_i^\dagger a_i, \\
\sigma_i^z = a_i^\dagger a_i
\]

(14)

for the sublattice of \(\bar{s}_i\) spins with \(s_i=1\), and

\[
\tau_i^+ = -s_2 + b_i^\dagger b_i, \\
\tau_i^- = \sqrt{2s_2} - b_i^\dagger b_i, \\
\tau_i^z = \sqrt{2s_2} - b_i^\dagger b_i
\]

(15)

for the sublattice of spins \(\bar{\tau}_i\) with \(s_2=\frac{1}{2}\), where the operators \(a_i\) and \(b_i\) are bosons. The spins \(\bar{s}_i\) are transformed in the similar way as Eq. (14) with bosonic operators \(c_i\) and \(c_i^\dagger\). Thus, the magnon spectra can be obtained by diagonalizing the Hamiltonian after performing the Fourier and Bogoliubov transformations. As shown in Fig. 2(a), the magnon spectra consist of a gapless branch \(\omega_{1,k}\) and two gapped ones \(\omega_{2,k}\) and \(\omega_{3,k}\). In the presence of a magnetic field \(h\), both \(\omega_{1,k}\) and \(\omega_{2,k}\) increase, while \(\omega_{3,k}\) decreases, indicating that \(\omega_{1,k}\) and \(\omega_{2,k}\) describe the magnons from \(S_G\) to \(S_G-1\) while \(\omega_{3,k}\) are those from \(S_G\) to \(S_G+1\). For \(J_2=0\), the spectra are reduced to a gapped and a gapless excitations, which agree exactly with those of the spin-(½, 1) mixed-spin chain. When \(J_2\) is set in, the gapless branch splits into \(\omega_{1,k}\) and \(\omega_{2,k}\). With increasing \(J_2\), both \(\omega_{2,k}\) and \(\omega_{3,k}\) enhance. It is found that the low-energy dispersions near \(k=0\) of the gapless branch \(\omega_{1,k}\) are insensitive to \(J_2\) but dominated by \(J_1\) in a wide range of the coupling ratio, which covers the result obtained from the RSRG.

The magnetic curve \(m(h)\) and low-energy gaps are then studied by the DMRG method. As shown in Fig. 2(b), \(m(h)\) has a plateau at the spontaneous magnetization \(m=\frac{J_1}{2}\), whose width \(\Delta_{MP}\) increases with increasing \(J_2\). In this figure, \(h_{c1}\) denotes the field where the plateau disappears, and \(h_s\) is the saturation field. For \(J_2=0\), \(\Delta_{MP}\) reduces to 1.75\(J_1\) of the spin-(½, 1) mixed-spin chain, which is exactly the gap of its massive magnon branch.\(^{11,12}\) The coupling dependence of \(\Delta_{MP}\) is illustrated in the inset of Fig. 2(b), showing that \(\Delta_{MP}\) increases almost as a linear behavior. The \(J_1\) dependence of \(\Delta_{MP}\) is also studied by taking \(J_2\) as the energy scale, which is not presented here. It is found that \(\Delta_{MP}/J_2\) varies rather slowly with \(J_1\), which means that \(\Delta_{MP}\) is mainly scaled by \(J_2\) in this case. The gap of the massive magnon branch \(\omega_{3,k}\) \(\Delta_{SW}\) is also shown in the inset of Fig. 2(b) in comparison to \(\Delta_{MP}\). The magnon gap obtained from the LSW appears to be smaller than \(\Delta_{MP}\), where the deviation increases for stronger \(J_2\). It appears that the LSW underestimates the magnon gap from \(S_G\) to \(S_G+1\).

We also compute the spin gap \(\Delta_{S_G+1}\) from the ground state to the lowest state in the \(S_G+1\) subspace, as shown in the inset of Fig. 2(b). Analogous to the spin-(½, 1) mixed-spin chain, \(\Delta_{S_G+1}\) is smaller than \(\Delta_{MP}\), indicating that \(\Delta_{S_G+1}\) is also not a magnon-like excitation. But, it has a similar behavior with coupling to \(\Delta_{MP}\), which can thus be used to describe the low-energy behaviors. The
spin gap from the ground state to the lowest state in the $S_G - 1$ subspace is computed, which is found always vanishing and is consistent with the gapless branch $\omega_{1,k}$.

Next let us discuss the spin-spin correlation function and local magnetization in ground states. Figure 2(c) shows the local magnetization as a function of lattice site for $h_{c2} < h < h_{c3}$. In the ground state, the spin correlation functions along the chain have a long-range order (LRO), and the spin fluctuations $\langle S_i^+ S_j^- \rangle$ decay rather rapidly (not presented here). Hence it is adequate to study only the local magnetization in the ground state. For $J_2 = 0$, it gives $m_t = -0.29248$ and $m_S = 0.79248$, exactly in agreement with the previous result. After tuning on $J_2$, the coupling dependence of sublattice magnetization is shown in Fig. 2(d). The pendant spin magnetization $m_t$ is suppressed by the quantum fluctuations after tuning $J_2$, while $m_S$ increases and approaches saturation for large $J_2$, confirming the results of the RSRG. The interesting phenomenon is the behavior of $m_t$. As shown by the arrow in Fig. 2(d), $m_t$ decreases for $J_2/J_1 < 1$, and turns to increase when $J_2/J_1 > 1$, which has a turning point at $J_2/J_1 = 1$, as suggested by the result of the RSRG. Meanwhile, it can be seen that $m_\sigma$ and $m_S$ intersect near $J_2/J_1 = 1$. The changes of coupling dependence of the magnetic moments near $J_2/J_1 = 1$ may be owing to the competition of the two AFM interactions.

B. $J_1 > 0, J_2 < 0$

To perform the LSW calculation, $\vec{a}_i$ and $\vec{r}_i$ spins are transformed as the form of Eq. (14) by the bosonic operators $(a_i, a_i^\dagger)$ and $(b_i, b_i^\dagger)$ with $s_1 = 1$ and $1/2$, respectively, while $\vec{S}_i$ are transformed as the form of Eq. (15) by $(c_i, c_i^\dagger)$ with $s_2 = 1$. As shown in Fig. 3(a), the spectra consist of a gapless and two gapped branches. In the presence of magnetic field, the gapless branch $\omega_{1,k}$ and the gapped branch $\omega_{2,k}$ increase, while the gapped branch $\omega_{2,k}$ decreases, indicating that $\omega_{1,k}$ and $\omega_{3,k}$ are the excitations from the sector $S_G$ to $S_G - 1$ while $\omega_{2,k}$ describes the excitations from $S_G$ to $S_G + 1$. It can be seen that the spectra in this case are quite different from those of case (A). The branch $\omega_{2,k}$ from $S_G$ to $S_G + 1$ is close to the gapless branch $\omega_{1,k}$ for the present case, and with increasing $|J_2|$, it increases slightly. The resulting distinctions in the thermodynamics would be explored in Sec. V. With changing the couplings, it is found that the low-energy dispersions of the gapless branch $\omega_{1,k}$ near $k = 0$ are dominated by $J_1$, which is consistent with the RSRG result.

The magnetic curve $m(h)$ and low-energy gaps are shown in Fig. 3(b). It can be seen that $m(h)$ exhibits two plateaux at $m = \frac{1}{3}$ and $\frac{2}{3}$. We denote the field where the $m = \frac{1}{3}$ plateau vanishes as $h_{c1}$, the lower and upper critical fields for the $m = \frac{2}{3}$ plateau as $h_{c2}$ and $h_{c3}$, respectively, and $h_s$ as the saturation field. With increasing $|J_2|$, the width of the $m = \frac{2}{3}$ plateau $\Delta_{MP}$ is enlarged slightly, while the $m = \frac{1}{3}$ plateau decreases and sares when $|J_2|/J_1 \geq 2.0$. It should be noted that in some quasi-one dimensional polymerized Heisenberg antiferromagnets, there might be a transition from the plateau state to the non-plateau state that is usually of the Kosterlitz-Thouless type. Such a transition point cannot be numerically determined accurately owing to the finite-size length of the chain. Therefore, in the present case, whether or not a plateau-non-plateau transition with couplings at the $m = \frac{2}{3}$ plateau exists is still uncertain from our DMRG numerical results. The coupling dependence of $\Delta_{MP}$ is illustrated in the inset of Fig. 3(b), showing that $\Delta_{MP}$ increases with enhancing $|J_2|$, and different from case (A), $\Delta_{MP}$ goes to saturate at large $|J_2|$, which suggests that $\Delta_{MP}$ is mainly scaled by $J_1$ for large $|J_2|/J_1$. The coupling dependence of the magnon gap $\omega_{2,k = 0}$ ($\Delta_{SW}$) is also shown in the inset of Fig. 3(b). It can be seen that the spin wave is capable of describing the coupling dependence of magnon gap qualitatively, though it underestimates the value like in the case (A). The spin gap $\Delta_{S_{G+1}}$ from the ground state to the lowest state in the $S_G + 1$ subspace is also computed. As shown in the inset of Fig. 3(c) $\Delta_{S_{G+1}}$ is less than $\Delta_{MP}$, indicating that it is also not a magnon-like excitation, and its behavior for different coupling ratios is consistent with $\Delta_{MP}$ and $\Delta_{SW}$.

The coupling dependence of sublattice magnetization in the ground states is shown in Fig. 3(c). As the quan-
tum fluctuations become strong after tuning \( J_2 \), the pendant spin magnetization \( m_\sigma \) decreases with increasing \(|J_2|\), which is analogous to case (A). However, the FM coupling has different effects on the spins in the chain compared with the AFM \( J_2 \). With increasing \(|J_2|\), both \( m_\tau \) and \( m_S \) increase slightly, and \( m_\tau \) does not show an extremum like in the case (A).

In the \( m=\frac{3}{2} \) plateau region (\( h_{c3}<h<h_{c3} \)), the local magnetization is shown in Fig. 3(d) for \(|J_2|/J_1=1\) as an example. It may be expected that all the local magnetic moments would increase from \( h_{c1}\) to \( h_{c2}\). However, by comparing the local magnetization below \( h_{c1}\) [Fig. 3(c)] and in the plateau [Fig. 3(d)], it is surprising to notice that \( m_\tau \) decreases from 0.3156 below \( h_{c1}\) to \(-0.0046\) in \( h_{c2}\). Therefore, the field dependence of sublattice magnetization is studied, as shown by \( m_S \), \( m_\tau \), and \( m_\sigma \) for \(|J_2|/J_1=1\) and 2.5 in Fig. 4. It can be seen that \( m_\tau \) decreases continuously from \( h_{c1}\) to \( h_{c2}\), while \( m_\sigma \) decreases in a short range above \( h_{c1}\). For a comparison, we also calculated the sublattice magnetization as a function of field for both the spin-(\( \frac{3}{2}, 1\) ) mixed-spin chain and the case (A). The results show that the above behavior is not seen. Therefore, this novel decreasing behavior may be owing to the competition between the FM and AFM interactions in a magnetic field.

C. \( J_1<0, J_2>0 \)

For \( J_1<0 \) and \( J_2>0 \), the HP transformations are applied on the spins \( \hat{S}_i \) and \( \hat{\tau}_i \) with the form of Eq. (14) by \((b_i, b_i^\dagger)\) and \((c_i, c_i^\dagger)\) for \( s_1=1 \) and \( \frac{1}{2}\), respectively, and that with the form of Eq. (15) is applied on \( \hat{\sigma}_i \) for \( s_2=1 \) with \((a_i, a_i^\dagger)\). As shown in Fig. 5(a), the spectra consist of a gapless (\( \omega_{1,k} \)) and a gapped (\( \omega_{3,k} \)) magnon branches from the sector \( S_G \) to \( S_G-1 \), as well as a gapped one (\( \omega_{2,k} \)) from \( S_G \) to \( S_G+1 \), which can be identified by the shifts of the branches with the magnetic field. It is noticed that the gapped branch \( \omega_{2,k} \) from \( S_G \) to \( S_G+1 \) is close to the gapless branch \( \omega_{1,k} \), which is similar to the case (B), but \( \omega_{2,k} \) has lower energies than \( \omega_{1,k} \) for large wave momenta \( k \) in the present case. With increasing \( J_2/J_1 \), \( \omega_{2,k} \) enhances and the intersected momenta of the two branches shift to higher values. A similar intersection of magnon branches has also been observed in the spin-(\( \frac{3}{2}, 1\) ) mixed-spin chain with AFM nearest-neighbor and FM next-nearest-neighbor interactions. The influences of this intersection on the thermodynamics would be discussed in the next section. For \( \omega_{1,k} \), it is found that the low-energy dispersions near \( k=0 \) are also dominated by \( J_1 \), which agrees with the RSRG analysis.

In Fig. 5(b), the magnetic curves \( m(h) \) for different couplings are shown. Similar to case (B), \( m(h) \) has two plateaux at \( m=\frac{1}{2} \) and \( \frac{3}{2} \), whose critical fields are denoted by the same symbols as the case (B). With increasing \( J_2/J_1 \), the width of the \( m=\frac{1}{2} \) plateau (\( \Delta_{MP} \)) extends, while that of the \( m=\frac{3}{2} \) plateau is enlarged, which differs from the case (B) where the \( m=\frac{3}{2} \) plateau decreases with increasing the coupling ratio. The inset of Fig. 5(b) shows the coupling dependence of the low-energy gaps \( \Delta_{MP}, \Delta_{SW}, \) and \( \Delta_{SG+1} \). It can be seen that the gaps behave similarly to those in the case (B). The gaps approach to the saturation for large \( J_2/J_1 \), indicating that they are mainly scaled by \( J_1 \) in the large \( J_2 \) limit. The
LSW also underestimates the magnon gap of $\omega_{2,k}$ as $\Delta_{SW}$ is smaller than $\Delta_{MP}$. $\Delta_{S_G+1}$ appears to be smaller than $\Delta_{MP}$, which means that the spin gap from the ground state to the lowest state in the subspace with $S_G + 1$ is also not a magnon-like excitation. In the ground states, the coupling dependence of the sublattice magnetization is displayed in Fig. 4(c). It can be seen that as the quantum fluctuations are induced by $J_2$, $m_S$ and $m_\tau$ decrease with increasing $J_2$, while $m_\sigma$ increases. In this case, the sublattice magnetic moments have more prominent variations with the change of the couplings than the previous cases.

In the $m=\frac{3}{2}$ plateau ($h_c< h< h_{c3}$), the local magnetic moments for $J_2/J_1=1$ are shown in Fig. 5(d). By comparing the local magnetization below $h_{c1}$ [Fig. 5(c)] and in the plateau [Fig. 5(d)], it is found that the novel decreasing feature of magnetization $m_\tau$ found in case (B) is also observed in the present case. The field dependence of sublattice magnetization is also studied. As illustrated in Fig. 5 for $J_2/J_1=0.5$ and 1.0, both $m_\sigma$ and $m_\tau$ have decreasing regions from $h_{c1}$ to $h_{c2}$. Comparing with the sublattice magnetization of case (B), we notice that the two sublattice magnetizations that have a decreasing region from $h_{c1}$ and $h_{c2}$ are those coupled by FM interactions, and the decreasing behavior is only observed below the $m=\frac{3}{2}$ plateau.

V. TEMPERATURE DEPENDENCE OF SUSCEPTIBILITY AND SPECIFIC HEAT

From the above results, it can be seen that although the three cases entirely exhibit FI ground states, the low-lying excitations and magnetic properties are rather distinct. Thus, in this section, the temperature dependences of zero-field magnetic susceptibility and specific heat are explored by the TMRG method. In the following calculations, the width of the imaginary time slice is taken as $\varepsilon=0.1$, and the error caused by the Trotter-Suzuki decomposition is less than $10^{-3}$. During the TMRG iterations, 120 and 200 states are retained for the evaluation of the susceptibility and specific heat, respectively, and the temperature is down to $k_B T=0.025|J_1|$ in general. The truncation error is less than $10^{-4}$ in all calculations.

The temperature dependence of the susceptibility $\chi$ and susceptibility temperature product $\chi T$ for the cases are shown in Figs. 7(a)-(c). For case (A), the susceptibility, as shown in the inset of Fig. 7(a), diverges as $T\to 0$ due to the gapless branch $\omega_{1,k}$ [Fig. 2(a)]. Upon lowering temperature, $\chi T$ decreases to a broad minimum at a temperature $T_{\text{min}}$, and then increases to a peak at low temperature $T_{\text{peak}}$. The minimum of $\chi T$ is an indicative of the FI-like behavior similar to that in the spin-($\frac{1}{2}$, 1) mixed-spin chain. With increasing $J_2/J_1$, $T_{\text{min}}$ shifts to higher temperatures, corresponding to the enhancement of the branches $\omega_{2,k}$ and $\omega_{3,k}$ with the increase of coupling ratios. Meanwhile, $\chi T_{\text{min}}$ increases for $J_2/J_1<1$ and decreases for $J_2/J_1>1$. The maximum of $\chi T_{\text{min}}$ is reached at $T_{\text{min}}=1.25J_1$ when $J_2/J_1=1$. It is also noticed that the $\chi T$ curves for different couplings intersect at the same temperature 1.25J_1, as shown by the arrow in Fig. 7(a). At low temperature, $\chi T$ does not diverge, like that in the spin-($\frac{1}{2}$, 1) mixed-spin chain, but has a sharp peak, which indicates that $\chi$ diverges equally or slower than $\frac{1}{T}$ as $T\to 0$. For the low-temperature peak, it is unveiled that $T_{\text{peak}}$ moves to higher temperatures with the increase of the height for $J_2/J_1<1$, while it approaches lower temperatures with the height decreasing for $J_2/J_1>1$. It can be seen that the finite-temperature magnetic properties have transition behaviors with the change of the couplings at $J_2/J_1=1$, which was also noted in the ground states in Sec. IV(A).

For case (B), $\chi$ also goes to infinity as $T\to 0$ owing to the gapless branch $\omega_{1,k}$ [the inset of Fig. 7(b)]. As shown in Fig. 7(b), $\chi T$ decreases rapidly to a minimum at $T_{\text{min}}$ with decreasing temperature, and then increases to a peak at lower temperature, which is quite different from that in the case (A). With increasing $|J_2|/|J_1|$, both $T_{\text{min}}$ and $\chi T_{\text{min}}$ enhance. As indicated by the arrow in Fig. 7(b), $\chi T$ curves for different couplings also intersect at a temperature $T\sim 1.15J_1$. At low temperature, both the peak temperature and height of $\chi T$ increase with increasing $|J_2|/|J_1|$. The peak suggests that $\chi$ diverges equally or slower than $\frac{1}{T}$ as $T\to 0$. Different from the case (A), the variation of $\chi T$ in the present case with FM coupled pendants does not exhibit a transition behavior. It can be seen that $J_2$ has a great impact on the low-lying excitations as well as the magnetic properties at finite temperature.

Figure 7(c) illustrates the behaviors of $\chi T$ for case (C). Although $\chi$ also diverges as $T\to 0$ [the inset of Fig. 7(c)], $\chi T$ has rather distinct behaviors from cases (B)
and (C) with $J_1>0$. For $J_2/|J_1|=0.2$, $\chi T$ increases to a broad maximum with decreasing temperature, and then declines. When $J_2/|J_1|>0.5$, a minimum of $\chi T$ emerges, and a small peak appears at a lower temperature. For $J_2/|J_1|>1$, $\chi T$ decreases to a minimum with declining temperature, showing the AFM feature, and then increases to a small peak, which is similar to that in the case (B). The minimum temperature $T_{\text{min}}$ also increases with enhancing $J_2/|J_1|$. The convergence of $\chi T$ as $T\to0$ indicates that $\chi$ diverges equally or slower than $1/|J_1|$ as $T\to0$ in this case. Compared with the above cases, no intersection of $\chi T$ is observed for the present case with $J_1<0$. It should be noted that the similar behavior of $\chi T$ has also been observed in the spin-(\(\frac{1}{2},1\)) AFM chain with FM next-nearest-neighbor coupling, which has an analogous low-lying excitations. As shown in Fig. 5(a), the gapped magnon branch $\omega_{2,k}$ has lower energies than the gapless branch $\omega_{1,k}$ for large wave momenta $k$. Thus, the low-lying excitations are dominated by $\omega_{2,k}$ for small $J_2$. With increasing $J_2/|J_1|$, $\omega_{2,k}$ enhances and $\omega_{1,k}$ gradually dominates the low-lying excitations. The branches $\omega_{1,k}$ and $\omega_{2,k}$ become analogous to that of the case (B) [Fig. 5(a)] for large $J_2/|J_1|$, yielding the behaviors of $\chi T$ for $J_2/|J_1|>1$ similar to that of the case (B) [Fig. 5(b)].

In Figs. 8(a)-(c), the temperature dependences of the specific heat for the three cases are shown explicitly. For case (A), the specific heat has a prominent double-peak
structure. When \( J_2/J_1 = 0.5 \), the high-temperature peak of specific heat is close to the peak temperature of that in the spin-\( (\frac{3}{2},1) \) mixed-spin chain. With further increasing \( J_2 \), the low-temperature peak shifts to higher temperatures when \( J_2/J_1 < 1 \), while it keeps nearly intact for \( J_2/J_1 > 1 \). Meanwhile, the high-temperature peak continuously moves to higher temperatures, which might be owing to the enhancement of the gapped branch \( \omega_{2,k} \) and \( \omega_{3,k} \).

The temperature dependence of specific heat for case (B) is shown in Fig. 5(b). When \( J_2/J_1 = 0.5 \), the specific heat has double peaks, and the high-temperature peak is also close to the peak temperature of that in the spin-\( (\frac{3}{2},1) \) mixed-spin chain. Compared with the specific heat of the case (A) with \( J_2/J_1 = 0.5 \) [Fig. 5(a)], it can be seen that the high temperature behaviors above the high-temperature peak of the two cases agree well with each other, but the low-temperature behaviors are distinct. With increasing \( J_2/J_1 \) for \( J_2/J_1 < 1 \), the low-temperature peak moves to higher temperature side, while the high-temperature peak keeps nearly intact. For \( J_2/J_1 = 1 \), the double peaks merge into a single peak, which moves to higher temperatures slightly with increasing \( J_2/J_1 \). Analogous to \( \chi(T) \), \( J_2 \) has also an essential effect on the behaviors of specific heat.

For case (C), the specific heat behaves quite differently from the above cases. For \( J_2/J_1 = 0.5 \), the specific heat shows a single peak instead of double peaks at low temperature. With increasing \( J_2 \) below \( J_2/J_1 = 1 \), the specific heat below the peak temperature keeps nearly unchanged, while the part above the peak temperature decreases more slowly, as shown in Fig. 5(c). For \( J_2/J_1 > 1 \), a high-temperature peak emerges, which moves to higher temperatures with increasing \( J_2/J_1 \). Meanwhile, the behaviors of specific heat below the low-temperature peak still retains nearly intact. The low-temperature peak seems to be insensitive to \( J_2 \), and is dominated by \( J_1 \).

For a comparison, we also calculated the thermal quantities by the LSW theory, which give rise to the similar behaviors for the three different cases. The results show that \( \chi(T) \) diverges as \( T \to 0 \), and the specific heat always exhibits double peaks. Although the obtained low-lying excitations are helpful to understand the thermodynamics, the quantitative results obtained from the LSW are not so good, which are thus not presented here.

VI. SUMMARY AND DISCUSSION

In this paper, the low-lying, magnetic and thermodynamic properties of the spin-\( (\frac{3}{2},1) \) decorated mixed-spin chain with spin-1 pendant spins are systematically studied for three cases: (A) \( J_1, J_2 > 0 \); (B) \( J_1 > 0, J_2 < 0 \); and (C) \( J_1 < 0, J_2 > 0 \) by jointly using a few different methods.

By means of the RSRG analysis, the low-energy effective Hamiltonians for each cases in strong and weak couplings are obtained. It is found that although the effective Hamiltonians are different for three cases, their magnon excitations from \( S_C \) to \( S_C - 1 \) are all FM and gapless, which agree with that of the spin-\( (\frac{3}{2},1) \) mixed-spin chain without pendants. The low-energy dispersions of the gapless branch near \( k = 0 \) are dominated by \( J_1 \) for each case, which is confirmed by the LSW results.

The low-lying excitations and magnetic properties are then investigated by the LSW and DMRG methods, respectively. The magnon spectra are found to consist of a gapless and a gapped branches from \( S_C \) to \( S_C - 1 \), as well as a gapped branch from \( S_C \) to \( S_C + 1 \), which have different features for three cases. For case (C), two low-energy branches have a novel intersection. In a magnetic field, case (A) has a \( m = \frac{1}{2} \) plateau, while both cases (B) and (C) exhibit two plateaux at \( m = \frac{1}{2} \) and \( \frac{5}{2} \). The low-energy gap of case (A) increases almost linearly with increasing the coupling ratio, while those of cases (B) and (C) increase and go to saturation for large \( |J_2| \), which implies that the low-energy gap of the case (A) is mainly scaled by \( J_2 \), and those of the cases (B) and (C) are scaled by \( J_1 \) for large \( |J_2| \). The sublattice magnetization of the spins coupled by FM interactions for cases (B) and (C) are found to decrease in some regions from \( h_{c1} \) to \( h_{c2} \) with the increase of the magnetic field, which may be attributed to the competition of the AFM and FM interactions in a magnetic field.

The zero-field thermodynamics are also explored by means of the TMRG method. It is unveiled that although \( \chi \) diverges as \( T \to 0 \), \( \chi(T) \) has rather different behaviors for each cases. For case (A), \( \chi(T) \) has a broad minimum and a peak at low temperature. The curves of \( \chi(T) \) for different couplings intersect at a common temperature \( 1.25J_1 \), and \( \chi(T) \) has a transition behavior with the couplings at \( J_2/J_1 = 1 \). For case (B), \( \chi(T) \) has a narrow minimum and a sharp peak at low temperature. The curves of \( \chi(T) \) for different couplings also intersect at a common temperature, but \( \chi(T) \) never show a crossing behavior. For case (C), \( \chi(T) \) has a broad peak for \( J_2/J_1 < 1 \), and exhibits a broad minimum and a peak for \( J_2/J_1 > 1 \), showing two distinct features with changing the couplings due to the intersection of two low-lying excitations. Compared with the spin-\( (\frac{3}{2},1) \) mixed-spin chain, there is a common feature for the three cases that \( \chi(T) \) converges as \( T \to 0 \), which implies that \( \chi \) diverges equally or slower than \( \frac{1}{T} \) as \( T \to 0 \).

The specific heat for case (A) has double peaks. For case (B), the specific heat has double peaks when \( |J_2/J_1| < 1 \), which merge into a single peak as \( J_2/J_1 > 1 \). For case (C), however, the specific heat has a single peak when \( J_2/J_1 < 1 \), while double peaks emerge when \( J_2/J_1 > 1 \). In a wide range of the coupling for case (C), the low-temperature peak appears to be insensitive to \( J_2 \), which mainly affects the high-temperature behaviors of the specific heat.

Based on the above results, it can be seen that the case (A) of the present system preserves some features of the spin-\( (\frac{3}{2},1) \) mixed-spin chain, while the cases (B) and (C) exhibit more novel exotic properties that have not been observed in the mixed-spin chains. We expect that
the magnetic and thermodynamic properties presented in this paper could be tested experimentally in future to unveil the effects induced by the pendant spins in the mixed-spin chains.

26 In order to investigate the low-temperature behavior of $\chi T$, we have performed the TMRG calculations to lower temperatures. However, as $\chi T$ decreases rather sharply as $T \to 0$, it is hard to determine exactly whether $\chi T$ converges to zero or just to a finite small value.
