1. Introduction

Recent rapid population growth and development of numerous industrial and technological sectors has led to increased emission of toxic and hazardous gases in the environment. Among these toxic and hazardous emissions, volatile organic compounds (VOCs) constitute the highest percentage owing to their significance as solvents and/or components in chemical, food, and healthcare industries. Acetone and ethanol are amongst the extensively used industrial VOCs despite their extreme flammability [1,2]. However, their fumes can be easily inhaled, and prolonged exposure to their vapours can result in serious health effects to humans and animals at large [3,4]. For instance, as the main non-methane organic pollutant, acetone concentrations higher than 173 ppm were reported to be responsible for severe central nervous system damage as well as causing headaches, fatigue, or narcosis [1]. As a result, threshold detection limit for any acetone gas sensor to be used for environmental safety and health purposes was set to 250 ppm, with an assumption of an 8 h exposure time weighted average [1,5,6]. Unlike acetone, the threshold detection limits of ethanol are relatively higher, being ≤1000 ppm over an 8 h exposure...
time weighted average [4,6,7]. Despite ethanol being a simple aliphatic alcohol and having significant roles in pharmacology for drug dissolution, in chemical synthesis, as a solvent and/or constituent compound, and in the food industry, its cytotoxicity is of great concern. This is because ethanol concentration levels above its threshold detection limit were found to lead to continuous lachrymation and coughing [4,8]. As a result, development of portable gas sensor devices exhibiting fast response and high sensitivity towards low concentrations of acetone and/or ethanol vapours is of great importance, both for indoor and outdoor applications, and has recently gained great prominence.

Over the last few decades, the use of various active materials including semiconducting metal oxides and nitrides, polymers, ionic membranes, and salts has been extensively explored for chemoresistive gas sensing devices [9,10]. The most popular groups are the semiconducting metal oxides and nitrides, as they provide an array of advantages such as low-power-consumption, flexibility, as well as simple architecture [11–14]. However, their high operating temperatures (>250 °C) and extreme sensitivity to humidity [11–13,15] hinder their fundamental application as high-performance acetone and/or ethanol sensing devices. Recently, the successful development and implementation of graphene-based VOCs sensors brought growing attention towards other members of the layered two-dimensional (2D) materials family, such as transition metal dichalcogenides (TMDs) and hexagonal boron nitride (hBN) nanosheets [13,16–20]. More specifically, nanocrystalline hBN nanosheets offer a route for improving sensitivity of gas sensors due to their high thermoconductivity, mechanical strength, and chemical stability [21,22]. Additionally, hBN nanosheets have good adsorption properties due to the partially ionic B–N chemical bonds and their 2D nature, which subsequently lead to high surface/volume ratio and enable total exposure of their atoms to the adsorbing gas molecules [23,24], thus rendering them excellent candidates as active materials in gas-sensing technology. Theoretically and experimentally, gas-sensing performance of hBN nanosheets was predicted for CH\textsubscript{4}, F\textsubscript{2}, NO\textsubscript{2}, H\textsubscript{2}, N\textsubscript{2}, O\textsubscript{2}, and CO\textsubscript{2}[20,25]. However, to the best of our knowledge, their experimental performance towards VOCs is rather scarce. Therefore, the current study aimed to explore hBN flakes as promising materials for detecting acetone and ethanol as the commonly used industrial VOCs. Additionally, the study hopes to provide useful information on the influence of the physicochemical properties of hBN flakes upon screening with acetone and ethanol.

2. Materials and Methods

2.1. Material Synthesis and Sensor Preparation

The hexagonal boron nitride (hBN) nanosheets were synthesised based on the reported procedure, whereby borazine was used a source for boron and nitrogen atoms, lithium nitride (Li\textsubscript{3}N, 99.4%, Alfa Aesar) [26,27], and barium fluoride (BaF\textsubscript{2}, 99%, Alfa Aesar) [28]. Typically, pure borazine monomer was polymerized at 55 °C to generate a colourless liquid polyborazylene (PBN) [28,29]. Then, 5 wt.% Li\textsubscript{3}N and 0–10 wt.% BaF\textsubscript{2} [30] were added to PBN, and the suspension was homogenised for 10 min. The suspension was then heated to 200 °C for 1 h, followed by annealing of the solid-state polymer for 1 h at 1200 °C under inert nitrogen (N\textsubscript{2}, 98%, Air Liquide, France) atmosphere [31,32]. The samples were then labelled as pristine hBN as well as 2.5 wt%, 5 wt%, and 10 wt% BaF\textsubscript{2} for samples obtained after modification with 2.5, 5, and 10 wt% BaF\textsubscript{2}. Finally, the pristine hBN and BaF\textsubscript{2}-modified hBN samples were evaluated for chemical vapour sensing properties by screening their as-fabricated devices against the polar aprotic (acetone) and the polar protic (ethanol) analytes (Table S1). For device fabrication, dispersions of 2 mg/mL of the hBN samples in 4 mg/mL of hexadecyltrimethylammonium bromide (CTAB) were sonicated for 30 min at 60 °C, then at 0 °C for a further 30 min [32]. The solutions were then stored at 0 °C so as to facilitate precipitation of hydrated crystals [33]. After careful decantation of the supernatant, −100 µL of the hBN dispersions were drop-casted onto an FR4 substrate containing interdigitated electrodes (ENIG-Electroless Nickel Immersion Gold, Micropress S.A.; active area −64 mm\textsuperscript{2}) and dried in an oven at 100 °C for 30 min (Scheme 1) [34,35].
The hBN nanosheets were then screened with the polar aprotic (acetone) and polar protic analytes (ethanol) for their potential as chemical vapour sensors.

Scheme 1. Representation of the sensor preparation on the interdigitated electrodes (a–c) and the device measurements chamber.

2.2. Characterisation

Prior to device fabrication, the morphological determination of the hBN samples was evaluated using the MET Phillips CM120 transmission electron microscope (TEM) at 120 kV after the nanosheets were supported onto a holey carbon mesh on a Cu grid. Their degree of crystallisation was studied using the HORIBA Jobin-Yvon Labram Evolution Raman spectrometer at the wavelength of 532 nm. The surface areas of the samples were investigated from the BELsorpII mini after degassing for 4 h at 100 °C and measuring adsorption and desorption isotherms of ultra-pure N\textsubscript{2} gas at 77 K. The chemoresistive measurements were recorded on an LCR meter (Agilent 4284A), and experiments were conducted in a glovebox under dry N\textsubscript{2} atmosphere.

3. Results

3.1. Structural Analysis

The morphology of the device active materials was investigated using transmission electron microscopy (TEM), which showed that the hBN samples were mainly overlapping, well-defined, and plate-like nanostructures of 0.89 ± 0.01, 2.9 ± 0.7, 3.3 ± 0.3, and 3.2 ± 0.7 µm in dimension for pristine hBN nanoflakes as well as the modified hBN samples after modification with 2.5, 5, and 10 wt.% of BaF\textsubscript{2}, respectively (Figure 1). The improvement in hBN nanosheets size upon addition of BaF\textsubscript{2} to the pre-ceramization mixture can be attributed to the faster melting of Li\textsubscript{3}N. This was facilitated by BaF\textsubscript{2} [28], consequently leading to improved crystallisation of hBN from PBN. As such, the effect of the addition
of BaF₂ to crystallinity and textual properties of the hBN nanosheets was studied using Raman spectroscopy and BET analysis.

![Figure 1](image-url)  
Figure 1. TEM images of (a) pristine hBN electrode materials and hBN samples after modification with (b) 2.5, (c) 5, and (d) 10 wt% BaF₂ [28].

The crystalline structural properties of the samples by Raman spectroscopy revealed formation of hBN nanostructures as evidenced by the presence of the first-order active Raman vibrating mode of hBN (E₂g) centred at \(-1365.4 \pm 1.6 \text{ cm}^{-1}\) (Figure 2a) [28,36]. Additionally, correlation of the finite-size effects within hBN with the inherent broadening of the Raman vibrational modes (Figure 2a, inset) showed the dependence of crystallinity of the hBN nanosheets to the addition of BaF₂. For instance, the bandwidths (FWHM) values decreased from 17.01 cm\(^{-1}\) for the pristine hBN sample to 11.07 cm\(^{-1}\) for the 5 wt% BaF₂ modified hBN sample, followed by a slight increase to 11.9 cm\(^{-1}\) recorded for the 10 wt% BaF₂ modified hBN sample. The narrowing of the bandwidths can be ascribed to formation of larger crystallites, as observed from the TEM micrographs (Figure 1c), as well as subsequent improvement in crystallinity and quality of the hBN nanosheets. As the hBN nanosheets are to be used as the active material in chemical sensor devices, determination of their surface areas and pore size distributions is very crucial in assessing their potential application within the field of sensor technology. Based on the multi-point Brunauer–Emmet–Teller (BET) method shown in Figure 2b, the samples exhibited a type II isotherm—an indication of the formation of macroporous or non-porous materials. As a result, the specific surface area was then determined to be 8.7 m²/g for the pristine hBN sample, whilst modification with 2.5, 5, and 10 wt% of BaF₂ led to surface areas of 3.5, 3.6, and 2.9 m²/g, respectively [28]. The decreasing surface area was expectedly due to the formation of larger crystalline planer flakes, thus limiting the amount of adsorption sites for N₂ and resulting in adsorption and desorption of the monolayer of N₂ predominantly on the material’s external rough surface on the basal planes. However, the results still indicate that the samples had sufficient adsorption sites for the chemical vapours, thus exhibiting potential for application in the chemical sensor technology.
3.2. Sensing Properties of the hBN Nanosheets

3.2.1. Resistance of the Sensors

The electrical resistance of the active materials as a function of the frequency with increasing concentration of an individual or a mixture of analytes was plotted so as to determine the optimum operating frequency for future experiments. From Figure 3 and Figure S1, great dependence of the sensor response to the structural properties of the hBN nanosheets was seen upon exposure to increasing concentrations of acetone and/or ethanol vapours. For instance, the rapid drop in resistance with increasing frequency for all samples can be ascribed to the presence of defects within the layered 2D structure of the hBN nanosheets [37]. Regardless of whether the nanosheets exhibited a well-defined morphology, as in the case of the 5 wt% BaF$_2$-modified hBN sample, or were defective, as seen with the pristine and the 2.5 wt% BaF$_2$-modified hBN samples, the presence of defects influenced the resistance of the resultant sensing device. We applied an alternating electric field due to the movement of charge carriers over relatively long distances so as to overcome the defects as well as the potential barriers of the layered 2D nanostructure [38]. As such, the best operating frequencies for the active materials in the modified hBN-based devices for acetone and/or ethanol were determined to be in the range of 1–3 kHz. The selection of the optimum operating frequency of the sensors was such that the LoD should have been lower whilst the sensitivity was higher (Figures S2–S6). The operating frequency was found to be better than and/or comparable to that of the commonly used active materials for detection of acetone and/or ethanol vapours, especially for room temperature-based sensors. For instance, Mutuma et al. reported operating frequencies of 3–10 kHz for differently nitrogen-doped hollow carbon sphere-based acetone sensors [39]. Moreover, Li et al. reported that zinc oxide-based nanosheets functioned best at the operating frequency of 3 kHz for detection of acetone, although the devices had to be heated to a temperature of 280 °C [40]. Generally, the results showed that the morphology of the hBN sensor material has a great influence on the sensing capability towards either acetone or ethanol vapours.

3.2.2. Performance of the Sensors

Based on the optimum operating frequency for each hBN-based sensor (Table 1), the performance of the devices was determined from their responses upon exposure to the vapours and the recoveries after removal of the analyte vapour. Figure 4 shows that all active materials exhibited excellent gas-sensing performance for individual acetone or ethanol vapours, as shown by response and recovery times, which were <100 s (Table S2) at optimum frequencies and exposure of 160 ppm analyte vapour. However, exposure to the

Figure 2. (a) Raman plots and (b) adsorption isotherms of pristine and 2.5, 5, and 10 wt% BaF$_2$-modified hBN samples. Inset: bandwidth of the Raman spectra as a function of BaF$_2$ wt% [28].
vapour mixture showed compromised response times for all samples except for the sensor devices based on the 5 wt% BaF$_2$-modified hBN samples ($t_{\text{res}} = 56$ s and $t_{\text{rec}} = 15$ s). This could be attributed to the poor interaction of both acetone and ethanol molecules on the basal planes of hBN flakes. Interestingly, for the majority of samples, the results indicated that the samples behaved as $p$-type semiconducting devices, shown by the increase in sensor resistance upon exposure to the analyte vapour and a depletion in sensor resistance on removal. On the contrary, the sensor performance for the devices fabricated out of 0 wt% BaF$_2$-modified hBN samples exhibited $n$-type semiconducting behaviour (Figure 4i), an indication of the prolonged depletion of the pre-generated holes as well as increased amount of hopping sites due to the defective nature of the 0 wt% BaF$_2$-modified hBN sample, thereby leading to increased conductivity upon exposure to the vapour mixture.

Figure 4. Responses and recovery times for devices fabricated after exposure and removal of 160 ppm of (a–d) acetone, (e–f) ethanol, and (i–l) acetone: ethanol vapours at optimum operating frequencies.

Furthermore, better performance was recorded for the hBN nanosheets that exhibited well-defined nanosheets morphology and structural properties (Figure 4c,d). For instance, response times less than 60 s were recorded for the 5 wt% and the 10 wt% BaF₂-modified hBN samples upon exposure to acetone vapour, whilst recovery times < 50 s were observed for both samples after removal of acetone (Table S3). The observations can be ascribed to the abundance of active surface adsorption sites on the basal planes of hBN nanosheets through the generation of more ionised adsorbed oxygen species (i.e., $\text{O}_2^-$, $\text{O}^-$, or $\text{O}^{2-}$, Scheme 2a,b) [41]. These adsorbed oxygen functional groups enabled faster conversion of acetone to carbon dioxide (Scheme 2(ci)) facilitated by the weak interaction of acetone molecules to the hBN surface. Furthermore, an improved saturation platform was observed for the 5 wt% BaF₂-modified hBN sample (Figure 4c) in comparison with other hBN-based devices. This could have been due to the presence of larger basal planes for the 5 wt% BaF₂-modified hBN sample, which enabled adsorption and coverage of a larger surface by the acetone molecules, thus leading to the observed faster response and recovery times for this sample. Owing to the large basal plane, faster response (56 s) and recovery (15 s) times were recorded upon exposure of the 5 wt% BaF₂-modified hBN-based sensor device to the mixture of acetone and ethanol. Moreover, this could be suggestive of the selectivity of this hBN-based sensor towards acetone in the presence of other VOCs.

On the other hand, the longer response times for pristine (~74 s) and 2.5 wt% BaF₂-modified (~61 s) hBN samples (Table S3) towards detection of acetone could be attributed to the retention of charge carriers as a result of prolonged electron-hopping effect generated by the structural defects. Subsequently, it can be suggested that these defects led to strong interaction of acetone molecules with the hBN surface, thereby resulting in longer recovery times of ~95 s and ~71 s for the pristine and the 2.5 wt% BaF₂-modified hBN samples, respectively. The retention of charge by defects was also shown by the extremely long
responses (−113 s) and recoveries (−75 s), thus translating to poor sensing performance of the 2.5 wt% BaF$_2$-modified hBN samples for detection and selectivity of VOCs. In the presence of a mixture of gases, roles of various surface structural properties were shown by the varying response and recovery times (Figure 4i–l). Expectedly, great sensing performance was exhibited by the 5 wt.% BaF$_2$ hBN-based device, as shown by the short response (−56 s) and recovery (−75 s) times. This indicated that the basal plane of the structurally improved 5 wt.% BaF$_2$ hBN nanoflakes (Figure 4k) enhanced the charge transfer to both analytes. On the other hand, the defective-prone 2.5 wt.% BaF$_2$ hBN (Figure 4j) nanostructures suffered a somewhat compromised sensing performance, as indicated by the extremely long response (−113 s) and recovery (−75 s) times. Interestingly, different sensing behaviour was shown by the variously modified hBN devices, with the pristine hBN device showing the n-type semiconducting behaviour (Figure 4i), whereas all the BaF$_2$-modified hBN devices displayed a p-type semiconducting behaviour (Figure 4j–l). The results show the significance of the structural properties in the manner of which each hBN active material transfer charge carried upon exposure to a mixture of ethanol and acetone vapours.

Scheme 2. Adsorption and reaction mechanism of acetone or ethanol on the hBN surface.

Regarding the performance of the sensors on exposure to ethanol vapour, the devices showed poor response times (−70–80 s, Table S3), an indication of poor transfer of charge carriers of the hBN active materials to the adsorbed ethanol molecules, therefore leading to a prolonged electron-hopping effect. Albeit, the sensing performance towards ethanol and/or acetone is governed mostly by the interaction of ethanol molecules with the gener-
ated adsorbed $O_2^-$, $O^-$, or $O^2-$ species [27,42], the long response times during exposure to ethanol for all devices are suggestive of the difficult absorption of the more polar ethanol molecules on the surface and the grain boundaries of hBN nanosheets in comparison with the adsorption mechanism of acetone. Moreover, owing to the two-step reduction process of ethanol on the active materials (Scheme 2(cii,iii)) [27,42], this could have contributed to the observed longer response times of ethanol in all samples. In this case, when the sensing device was exposed to ethanol vapour, the reduced gas molecules were first oxidised into an acetaldehyde molecule (Scheme 2(cii)), which then required more oxygen anions for the final conversion into carbon dioxide and water (Scheme 2(ciii)). However, the shorter recovery times of $-34$ s, $-56$ s, $-34$ s, and $-40$ s for pristine, 2.5 wt%, 5 wt%, and 10 wt% BaF$_2$-modified hBN-based devices (Table S3), respectively, are suggestive of the weak interaction of the ethanol molecule with the basal planar hBN surface. In hindsight, the results show that layered hBN nanosheets with well-defined morphologies and improved properties can have excellent functionality as good resistance-based VOCs sensors, similar to their zero-bandgap graphene, small band-gap semiconducting transitional metal dichalcogenides (TMDs), and conducting mxenes counter-parts [16,43,44].

3.2.3. Determination of Sensing Parameters

At the chosen optimum operating frequencies, sensing parameters of each hBN-based device, given by the concentration limit of detection (LoD, Equation (S2)) and the sensitivity ($S$, Equation (S3)), were estimated from the plots of sensor resistance and/or response ($AR/R_0$, Equation (S4)) against the concentration of analyte of interest (Figure 5 and Figures S2–S4). As seen in Figure 5, the sensor responses were increasing with either acetone or ethanol vapour concentration, an indication that the hBN-based nanosheets in this study were $p$-type semiconducting in nature. However, the structural morphology of the hBN nanosheets was found to play a profound role in the overall sensing performance of the devices. For instance, very low sensitivity and extremely high LoD values were determined for the devices based on the hBN nanosheets exhibiting improved structural properties. In particular, $4.2 \times 10^{-4}$ ppm$^{-1}$ and 460 ppm (Table 1) were estimated as the sensitivity and the LoD values for the sensing device based on 5 wt% BaF$_2$-modified hBN nanosheets for acetone detection, whilst ethanol detection registered $4.5 \times 10^{-4}$ ppm$^{-1}$ and 543 ppm, respectively. Similarly, sensitivity and LoD values were estimated for the sensing device based on 10 wt% BaF$_2$-modified hBN nanosheets towards the detection of both acetone and ethanol (Table 1). Despite the 5 wt% BaF$_2$-modified hBN-based devices displaying fast response and recovery times upon exposure to acetone and ethanol (Figure 4c,g), their overall poor sensing performance could be attributed to the weak interactions between the carbonyl groups on the analyte molecules with the hBN basal surface. A similar argument could also be used for the observed LoD (144 ppm$_{\text{acetone}}$ and 134 ppm$_{\text{ethanol}}$) and sensitivity ($7.2 \times 10^{-3}$ ppm$^{-1}$ acetone and $1.9 \times 10^{-3}$ ppm$^{-1}$ ethanol) values for the 10 wt% BaF$_2$-modified hBN-based devices on exposure to increasing concentrations of both acetone and ethanol vapours. Interestingly, slight improvement in the sensing performance of the hBN nanosheets exhibiting improved structural properties was observed upon exposure to the mixture of ethanol and acetone (Table 1 and Figure S2c,d). For instance, low LoD values of 197 ppm and 439 ppm were estimated for 5 wt% and 10 wt% BaF$_2$-modified hBN-based devices, whereas higher sensitivities were determined to be $7.0 \times 10^{-3}$ ppm$^{-1}$ and $1.0 \times 10^{-2}$ ppm$^{-1}$, respectively. This is suggestive of enhanced transfer of charge carriers. Moreover, the defects were observed to have little impact on the sensing performances of 0 wt% and 2.5 wt% BaF$_2$-modified hBN-based devices, as high sensitivity and low LoD values were estimated upon detection of a VOCs vapour mixture of ethanol and acetone. In spite of the retention of charge carriers by defective sites, these acted as capture sites for the adsorption of a larger volume of analyte molecules, thus corresponding to low LoD values of 30.4 ppm and 18 ppm for 0 wt% and 2.5 wt% BaF$_2$-modified hBN-based devices, respectively.
Figure 5. Sensor response versus concentrations of (a–d) acetone and (e–h) ethanol at optimum operating frequencies.

On the other hand, pristine and defective 2.5 wt% BaF₂-modified hBN samples registered lower concentration limits of detection and high sensitivity values (Table 1). The lower values are indicative of improved sensing performance, which could be ascribed to the stronger surface interaction of the analyte molecules with the hBN nanoflakes. Furthermore, the abundant nitrogen and/or boron vacancies (VN or VB) in the defective structure of hBN could have acted as electron capture sites upon exposure to either acetone or ethanol [45,46], thereby resulting in improved sensitivity. Interestingly, regardless of the structural properties was observed by the sensitivity towards the detection of volatile organic compounds. In summary, the results indicated the formation of well-defined morphology hBN nanosheets greatly hindered their performance towards the detection of volatile organic compounds. In summary, the results indicated that our synthesised hBN nanosheets are potential candidates for room temperature chemoresistive gas sensors (Table 2), as the obtained values were comparable to those of graphene, conductive metal oxides, mxenes, as well as transition metal dichalcogenides (TMDs) [25]. Moreover, the sensors were found to be stable even after 18 months of storage as approximately 75%, 50%, 92%, and 8% decreases in sensor responses were observed for 0 wt%, 2.5 wt%, 5 wt%, and 10 wt% modified hBN samples after exposure to 180 ppm of acetone (Figure S7). Likewise, the effect of the structural properties was observed by the sensitivity values, which were recorded after 18 months and were found to be 0.04, 0.1, 0.04, and 0.12 as well as 0.4, 2.3, 0.06, and 0.2 × 10⁻² ppm⁻¹ against acetone and ethanol for 0 wt%, 2.5 wt%, 5 wt%, and 10 wt% modified hBN samples, respectively (Table S4). The 5 wt%-BaF₂ hBN samples produced reproducible results in comparison with other active materials even after 18 months of storage, and this can be attributed to the improved crystallinity of the nanoflakes, which thus limited and/or slowed the degradation of the hBN nanostructures.

Our reported sensor performance, specifically for the pristine and the 2.5 wt% BaF₂ modified hBN samples towards acetone or ethanol, showed better and/or relatively comparable LoD values to those of their 2D counterparts such as graphene oxide, transition metal dichalcogenides (TMDs), and mxenes (Table 2). For instance, the pristine and the 2.5 wt% BaF₂ modified hBN-based sensors showed significantly lower LoD values than sensors based on TMDs and metal oxides for acetone and ethanol molecules; however, they
were still relatively higher than those of graphene-and mxene-based sensors [16,46–55]. Better LoDs in mxene- and graphene-based sensors were attributed to the abundance of oxygenated and/or ligand functional groups, which ultimately facilitated an improved adsorption–desorption mechanism of the VOC molecules. On the other hand, improvement in structural properties upon addition of BaF$_2$ to the preceramic mixture of hBN, especially 5 wt%, greatly compromised their sensing performance towards VOCs. This was ascribed to the lack of defect sites, which subsequently led to fewer oxygenated functional groups, thereby affecting the sensing properties of the 5–10 wt% BaF$_2$ modified hBN-based sensors. The important point in this work is the low LoD value for the defective hBN samples towards detection of both VOCs compared to other reports in literature. Generally, the results indicate that, with controlled improvement in the structural properties of hBN, enhanced sensing performance of hBN nanosheets towards both protic and aprotic VOCs can be achieved.

| Analyte | Active Material | Sensor Type         | Conc. Range (ppm) | Temp. (°C) | LoD (ppm) | Ref  |

MoS$_2$ → molybdenum disulphide; ZnO → zinc oxide; hBN → hexagonal boron nitride; BaF$_2$ → barium fluoride; rGO → reduced graphene oxide; Ti$_3$C$_2$T$_x$ → bimetallic Mxene; SnO$_2$ → tin oxide; GO → graphene oxide; WO$_3$ → tungsten oxide; gC$_3$N$_4$ → graphitic carbon nitride; α-Fe$_2$O$_3$ → alpha ferric oxide.

4. Conclusions

Following the modification of hexagonal boron nitride (hBN) flakes produced through addition of barium fluoride (BaF$_2$) in a polymer-derived ceramics (PDCs) synthesis technique, their sensing performance towards volatile organic compounds (VOCs) was then investigated. The results showed that the sensing devices fabricated from the hBN nanostructures were active for acetone or ethanol detection, and their sensing performance was dependent on the structural properties of the nanostructures. For instance, the pristine and the 2.5 wt% BaF$_2$ modified hBN-based sensors exhibited improved sensing performance towards both analytes. This was shown by the low LoDs (−43–86 ppm$_{acetone}$ and −30–62 ppm$_{ethanol}$) and the high sensitivities (−1.8–2.1 × 10$^{-2}$ ppm$^{-1}$ acetone and −1.5–1.6 × 10$^{-2}$ ppm$^{-1}$ ethanol), which can be attributed to the defective domains on these samples, which subsequently provided an abundance of adsorption sites for the analyte molecules of interest. Despite the rapid response and recovery times for the 5–10 wt% BaF$_2$ modified hBN-based sensors, the improved 2D morphology for the hBN flakes was found to hinder the good sensing performance of hBN nanostructures towards acetone and ethanol. This was highlighted by the high LoD values of −144–460 ppm and −134–543 ppm, with extremely poor sensitivities of −0.042–0.72 × 10$^{-2}$ ppm$^{-1}$ and −0.045–0.19 × 10$^{-2}$ ppm$^{-1}$
for acetone and ethanol for the structurally improved 5–10 wt% BaF₂-modified hBN flakes, respectively. The loss in sensor activity was also attributed to the relatively low surface areas of the hBN nanostructures (2.9 to 3.5 m²/g). Overall, the study demonstrated that the structural properties of the hBN flakes should be taken into serious consideration prior to the design of room temperature sensing devices for VOCs.
