(Dated: October 26, 2009)

Low-field magnetotransport measurements on a high mobility ($\mu = 110,000$ cm$^2$/Vs) two-dimensional (2D) electron system on a H-terminated Si(111) surface reveal a sixfold valley degeneracy with a valley splitting $\leq 0.1$ K. The zero-field resistivity $\rho_{xx}$ displays strong temperature dependence for $0.07 \leq T \leq 25$ K as predicted for a system with high degeneracy and large mass. We present a method for using the low-field Hall coefficient to probe intervalley momentum transfer (valley drag). The relaxation rate is consistent with Fermi liquid theory, but a small residual drag as $T \rightarrow 0$ remains unexplained.

PACS numbers: 73.40.-c, 73.43.Qt, 71.70.Di

Two-dimensional electron systems (2DESs) with additional discrete degrees of freedom (e.g. spin, valleys, subbands, and multiple charge layers) have attracted recent interest due to the role of such variables in transport and in the formation of novel ground states in the the quantized Hall regime. In particular, systems with conduction band valley degeneracy display a rich parameter space for observing and controlling 2DES behavior. Among multi-valley systems, electrons on the (111) surface of silicon are especially notable because effective mass theory predicts the conduction band valley degeneracy display a rich parameter space for observing and controlling 2DES behavior. The sample was probed via standard Van der Pauw measurements (Fig. 2 inset) using low frequency (7-23 Hz) lock-in techniques in both He-3 and dilution refrigerators.

At $B=0$, $\rho_{xx}$ is strongly affected by $T$ (Fig. 1b) and at low $T$ displays a metal-insulator crossover near $n_{s\text{crit}} = 0.9 \times 10^{11}$ cm$^{-2}$. Above this density, the device is clearly metallic, with $\rho$ decreasing by a factor of 3-4 from 5 to 70 mK at $n_s = 0.9 \times 10^{11}$ cm$^{-2}$. Compared with Si(100), Si(111) has a larger density of states effective mass ($m_{111}^* = 0.35m_e$ vs. $m_{100}^* = 0.190m_e$), and a larger $g_\nu$ (6 vs 2) would lead to a much larger density of states at the Fermi level. Consequently, electrons on Si(111) should display much stronger screening and therefore a stronger $T$ dependence of $\rho_{xx}$. Our observations appear to be qualitatively consistent with such predictions. At intermediate densities, $\rho_{xx}$ is non-monotonic in $T$, similar to behavior discussed elsewhere. The data presented in the remainder of this paper was taken at a fixed density of $n_s = 6.7 \times 10^{11}$ cm$^{-2}$.

The low-$B$ SdH oscillations of the present sample reveal minima at filling factors $\nu = \pm m_s/eB$ spaced by $\Delta \nu = 12$ below 0.5 $T$ and $\Delta \nu = 6$ above this point (Fig. 2). Note, however, that the 12-fold-degenerate minima in $\rho_{xx}$ occur at odd multiples of 6 (54, 66, 78, 90...) rather than even as would be expected if the effective mass $m^*$ and $g$-factor $g^*$ are equal to their band values. This may indicate a $B$-dependent valley splitting and/or enhanced Zeeman splitting at low fields (though unlike the spin-dominated gaps seen in Si(100) and Si(111) MOSFETs, our observations persist far into the metallic regime). At $B > 2$ T valley degeneracy lifts, eventually resulting in...
integer quantum Hall features appearing at intervals of $\Delta \nu = 1$ from $\nu = 10$ to 1.

Another effect of the weak valley splitting is the observation of isotropic transport ($R_{xx} = R_{yy}$ to within $\approx 7\%$) as shown in Fig. 2 (inset). If charge is evenly distributed among a suitably symmetric set of valleys (discussed below), the total resistivity becomes isotropic. A lifting of the valley degeneracy can shift the valley population into an asymmetric distribution, causing anisotropy in $\rho$ and other transport effects. While previous H-Si(111) devices have shown this anisotropy,[8] the absence of such asymmetry in the device presented here suggests that the valley splitting is quite small at $B = 0$. When a small $B$ is applied, the baseline $R_{xx}$ and $R_{yy}$ values remain similar but the SdH response is different: the $\rho_{yy}$ minima appear out of phase with the $\rho_{xx}$ minima while retaining the essentially 12-fold periodicity (Fig. 2). This may result from a slight population imbalance due to a very small valley splitting, which may increase further for $B > 0$.

In order to provide a quantitative bound on the zero-field valley splitting, we measure the intrinsic (i.e., $B$-independent) level broadening, which is normally characterized in terms of the Dingle temperature $T_D$, or equivalently by the quantum lifetime $\tau_q = h/2\pi k_B T_D$, by examining the evolution of the SdH oscillations as a function of $T$. If the energy level spacing is $E_{gap} = \delta B$ (for some constant $\delta$) the amplitude of these oscillations should be $R_0 e^{-2\pi^2 k_B T_D/\delta B \xi} / \sinh(\xi)$ where $\xi = 2\pi^2 k_B T_D/\delta B$.[9,11] Thus from the $T$ dependence of the amplitudes (unaffected by the phase anomalies noted above) we can determine $\tau_q$ as well as the $B$-dependent gap size $\delta$.

From the $\rho_{xx}$ oscillations we obtain a value of $\delta = (2.69 \pm 0.11) \, \text{K}/\text{T}$ (Fig. 3). Because our gaps occur at odd multiples of six, the simplest analysis would treat them as spin gaps, which would correspond to an enhanced $g^* = 4.0 \pm 0.2$. However, the anisotropy that emerges when $B > 0$ suggests $B$-dependent valley splitting is also present, confounding a simple interpretation of $\delta$. Regardless of the gaps’ origin, from $\delta$ we can compute the quantum lifetime $\tau_q \approx 12 \, \text{ps}$, which is quite close to the transport lifetime $\tau_0 \approx 18 \, \text{ps}$ obtained from $\rho_{xx} (B = 0)$ as described below; this corresponds to a $T_D$ (and thus an upper bound on the valley splitting) of 0.1 K.

Having established the sixfold valley degeneracy of our 2DES at $B = 0$, we now turn to the role of this degeneracy in carrier scattering; in particular we consider the effect of momentum exchange between valleys on low $B$ transport. Semiclassical transport in multiple anisotropic valleys can result in additional (non-oscillatory) $B$ dependence in both $\rho_{xx}$ and $\rho_{xy}$ at low fields (seen, for example, in the overall positive slope of the data in Fig. 3). This low $B$ behavior can provide information about valley-
valley interaction effects. To see this, first consider the case of non-interacting valleys that are identical up to rotations $Z(\theta)$ in the $x$-$y$ plane for some $\theta < \pi$ that defines the rotational symmetry of the whole set. The Drude resistivity for a single valley with proportional density $n_s/g_v$ for coordinates aligned to the symmetry axes of the valley is given by

$$\rho_0 = \frac{g_v}{n_s e} \left( \frac{m_1}{e \tau_0} - B \right), \quad (1)$$

where $\tau_0$ is the transport lifetime associated with momentum transfers from the 2DES to the lattice (both in-plane and inter-valley scattering). The resistivity of the $j^{th}$ valley is $\rho_j = Z(j\theta)\rho_0 Z(-j\theta)$ and the total $\rho$ will be

$$\rho = \left( \sum_j \rho_j \right)^{-1} = \frac{1}{n_s e} \frac{\Phi + (\omega_c \tau_0)^2}{\Phi (\omega_c \tau_0 + 1)^2 + (\omega_c \tau_0)^2} \left( \frac{\tilde{m}}{e \tau_0} - B \right), \quad (2)$$

where $\tilde{m} \equiv (m_1 + m_2)/2$, $\omega_c = eB/m^*$ is the cyclotron frequency, $m^* = \sqrt{m_1 m_2}$, and we define $\Phi \equiv (\tilde{m}/m^*)^2$. For $\omega_c \tau_0 \gg 1$ both $\rho_{xx}$ and $\rho_{xy}$ are given by their respective classical values $\rho_{xx} = \tilde{m}/e^2n_s\tau_0$ and $\rho_{xy} = B/e_n$. At $B = 0$ however, both are suppressed by the factor $\frac{1}{\Phi} \leq 1$, with equality only in the case of isotropic valleys ($m_1 = m_2$). In the case of Si(111) (using the band masses $m_1 = 0.190m_e$, $m_2 = 0.674m_e$, $m^* = 0.358m_e$, we find $\frac{1}{\Phi} = 0.686$.

The preceding discussion treats the valleys as independent channels. Strong valley-valley coupling, as might arise from Coulomb interactions between electrons, will tend to suppress this correction as all electrons move in concert. To make this idea more rigorous, we model intervalley effects as a drag interaction between valleys that conserves total 2DES momentum while damping the relative momenta between valleys. This is distinct from intervalley scattering probed via weak localization, which requires a short-range interaction potential that does not conserve 2DES momentum. Following the kinetic approach used in [13] for multi-band systems we obtain a set of coupled equations:

$$\frac{M_j v_j}{\tau_0} = e(E + v_j \times B) + \frac{1}{\tau_{vv}} \sum_{k \neq j} (M_{jk}(v_k - v_j)). \quad (3)$$

Here $M_j$ is the mass tensor of the $j^{th}$ valley, $M_{jk}^{-1} = M_j^{-1} + M_k^{-1}$ is the reduced mass tensor of the $j$-$k$ system, and $\tau_{vv}$ is the drag relaxation time (assumed constant and isotropic). Combining opposite valleys (which have the same $M_j$), we have three valley pairs. Substituting $\tilde{J}_k = n_k e v_k = n_k e v_k/3$ we then solve the equation $E = \rho \tilde{J} = \rho (J_1 + J_2 + J_3)$ for $\rho$. This gives

$$\rho_{yx} = -\rho_{xy} = \frac{B}{n_s e} \frac{\Lambda \frac{\tilde{m}}{m_1} \tau_{xx} (\omega_c \tau_0 + 1) (\Lambda \frac{\tilde{m}}{m_2} \tau_{xx} + 1) + (\omega_c \tau_0)^2}{\Phi (\omega_c \tau_0 + 1)^2 + (\omega_c \tau_0)^2} \quad (4)$$

and

$$\rho_{xx} = \rho_{yy} = \frac{\tilde{m}}{n_s e^2 \tau_0} \frac{\Phi (\omega_c \tau_0 + 1) (\Lambda \frac{\tilde{m}}{m_2} \tau_{yy} + 1) + (\omega_c \tau_0)^2}{\Phi (\omega_c \tau_0 + 1)^2 + (\omega_c \tau_0)^2}, \quad (5)$$

where $\Lambda \equiv 6 \det(M_{jk})/\det(M_j) = 6/(3\Phi + 1)$. In the absence of intervalley interaction, $\frac{\tilde{m}}{\tau_{vv}} \to 0$ and we recover Eq. (2). Conversely, when $\tau_{vv} \ll \tau_0$ we effectively wash out the multi-valley correction. Thus by measuring $\rho_{xx}$ and $\rho_{xy}$ in the $B = 0$ limit we can solve for $\tau_{0}^{-1}$ and $\tau_{vv}^{-1}$.

Figure 4 (left axis) shows such a measurement of $r_H \equiv \rho_{xy}/(B/e_n)$ vs. $T$, averaging results from orthogonal directions (Fig. 2) to remove mixing from $\rho_{xx}$ and $\rho_{yy}$. We determine the density $n_s = 6.7 \times 10^{11} \text{cm}^{-2}$ from $R_{xx}$ minima at $\nu = 18$ and $\nu = 6$ and find it to be insensitive to $T$. $B$ was held fixed at $\pm 50 \text{mT}$ while $T$ was swept both up and down to ensure consistency. Taking a slope from these points gives a measure of $r_H$ near $B = 0$. Above 5 K, $r_H$ is very close to its classical value, while below 5 K $r_H$ drops rapidly with $T$ before settling to a value of 0.65 at $T = 90 \text{mK}$. Interestingly, 0.65 is less than the lower bound of 0.686 predicted for the drag-free limit. Because the measurement is based on data taken at $B \neq 0$, we expect this to be an overestimate of $r_H$, especially at low $T$ where the $\omega_c \tau_0$ terms in Eqs. (4) and (5) are largest. The simplest adjustment we can make is to model our data incorporating this discrepancy is to allow $\tau_{vv}^{-1}$ to approach a constant negative value at low $T$.

On the right axis of Fig. 4 we plot the $T$ dependence of the extracted $\tau_{vv}^{-1}$ (364 ps)$^{-1}$ (offsetting $\tau_{vv}^{-1}$ by the base temperature value to remove the divergence) as well as
the lattice scattering rate $\tau_0^{-1}$. The dashed magenta line plots the $T$-dependent electron-electron ($e-e$) scattering rate theoretically expected\textsuperscript{12} for a single-valley 2D Fermi liquid $\tau_{e-e}^{-1} \sim E_F^2 (T/T_F)^2$, with a prefactor of 1.9 determined by fitting. Although earlier work has identified the sensitivity of $r_H$ to $e-e$ interactions\textsuperscript{4,14,18,19} such corrections are quite small ($\sim 1-4\%$) at high densities ($n_s \gg n_{sat}$). Furthermore, these models predict $r_H \to 1$ in the $T \to 0$ limit, whereas our model treats the multi-valley effects of Eq. (2) as intrinsic at $T = 0$.

Several open questions remain regarding this data. First is the dominance of the odd gaps and the low-field phase anisotropy in the SdH data. Although the experimental setup did not allow for tilted B field measurements, such experiments could help identify the roles of cyclotron, spin, and valley splitting in forming these gaps. Second, we note the disparity between the measured $r_H$ at base temperature and the lower bound given by our model, which we have presented in terms of negative drag for mathematical simplicity. Known corrections to $\rho_{xy}$ for instance due to disorder, would increase $r_H$ not decrease it as reported here. Negative drag has been discussed as a possible consequence of electron correlation in bilayer systems\textsuperscript{20,21,22}. Small sample anisotropies (neglected in our model) could also play a role. Another possibility is that anisotropic enhancement of $m^*$ could change the $T = 0$ limit of Eq. (4) (note that isotropic enhancement would not change $r_H$, which depends only on mass ratios). Alternatively, a more sophisticated theory of valley-valley interactions could modify the $T \to 0$ limit of our simple model.

Finally, we consider why sixfold degeneracy persists in this device given the ease with which mechanisms such as misorientation, disorder, and strain can lift this degeneracy\textsuperscript{31,10,23} and that previous work on H-Si(111) found the $g_e = 6$ ground state split into a low energy $g_e = 2$ band with a $g_e = 4$ band ~ 7 K above it\textsuperscript{8}. If that gap was in fact produced or enhanced by surface disorder, perhaps the higher mobility of the present sample can account for the difference. Further work on the relationships between surface preparation, device mobility, and valley splitting is presently underway.
