We present a systematic stability analysis for the two-dimensional Hubbard model, which is based on a new renormalization group method for interacting Fermi systems. The flow of effective interactions and susceptibilities confirms the expected existence of a $d$-wave pairing instability driven by antiferromagnetic spin fluctuations. More unexpectedly, we find that strong forward scattering interactions develop which may lead to a Pomeranchuk instability breaking the tetragonal symmetry of the Fermi surface.

PACS: 71.10.Fd, 71.10.-w, 74.20.Mn

The two-dimensional Hubbard model has attracted much interest as a promising prototype model for the electronic degrees of freedom in the copper-oxide planes of high-temperature superconductors, since it has an antiferromagnetically ordered ground state at half-filling and is expected to become a $d$-wave superconductor for slightly smaller electron concentrations.

Although the Coulomb interaction in the cuprate superconductors is rather strong, the tendency towards antiferromagnetism and $d$-wave pairing is captured already by the 2D Hubbard model at weak coupling. Conventional perturbation theory breaks down for densities close to half-filling, where competing infrared divergences appear as a consequence of Fermi surface nesting and van Hove singularities. A controlled and unbiased treatment of these divergencies cannot be achieved by standard resummations of Feynman diagrams, but requires a renormalization group (RG) analysis which takes into account the particle-particle and particle-hole channels on an equal footing.

Early RG studies of the two-dimensional Hubbard model started with simple but ingenious scaling approaches, very shortly after the discovery of high-$T_c$ superconductivity. These studies focussed on dominant scattering processes between van Hove points in $k$-space, for which a small number of running couplings could be defined and computed on 1-loop level. Spin-density and superconducting instabilities where identified from divergencies of the corresponding correlation functions.

A major complication in two-dimensional systems compared to one dimension is that the effective interactions cannot be parameterized accurately by a small number of running couplings, even if irrelevant momentum and energy dependences are neglected, since the tangential momentum dependence of effective interactions along the Fermi surface is strong and important in the low-energy limit. This has been demonstrated in particular in a 1-loop RG study for a model system with two parallel flat Fermi surface pieces. Zanchi and Schulz have recently shown how modern functional renormalization group methods can be used to treat the full tangential momentum dependence of effective interactions for arbitrary curved Fermi surfaces. Most recently, Salmhofer has derived an improved version of this field theoretic approach. The resulting flow equations are particularly suitable for a concrete numerical evaluation. To compute physical instabilities, we have derived the corresponding flow equations for susceptibilities.

In this letter we present results for the flow of susceptibilities as obtained by applying Salmhofer’s renormalization group method to the two-dimensional Hubbard model with nearest and next-nearest neighbor hopping on a square lattice. The expected existence of a $d$-wave pairing instability driven by antiferromagnetic spin fluctuations is thereby confirmed beyond doubt. More unexpectedly, we find that strong forward scattering interactions develop which may lead to a Pomeranchuk instability breaking the tetragonal symmetry of the Fermi surface.

The one-band Hubbard model describes tight-binding electrons with a local repulsion $U > 0$. Here $c_i^\sigma$ and $c_i^\dagger$ are creation and annihilation operators for fermions with spin projection $\sigma \in \{\uparrow, \downarrow\}$ on a lattice site $i$, and $n_{j\sigma} = c_i^\dagger c_i^\sigma$. A hopping amplitude $t$ between nearest neighbors and an amplitude $-t'$ between next-nearest neighbors on a square lattice leads to the dispersion relation

$$\epsilon_k = -2t(\cos k_x + \cos k_y) - 4t' \cos k_x \cos k_y$$

for single-particle states. This dispersion relation has saddle points at $k = (0, \pi)$ and $(\pi, 0)$, which generate logarithmic van Hove singularities in the non-interacting density of states at the energy $\epsilon_{vH} = 4t'$. For $t' = 0$, $\epsilon_k$ has the nesting property $\epsilon_{k+Q} = -\epsilon_k$ for $Q = (\pi, \pi)$, which leads to an antiferromagnetic instability for arbitrarily small $U > 0$ at half-filling.
The RG equations are obtained as follows (for details, see Salmhofer [8] and Ref. [1]). The infrared singularities are regularized by introducing an infrared cutoff \( \Lambda > 0 \) into the bare propagator such that contributions from momenta with \( |\mathbf{k} - \mu| < \Lambda \) are suppressed. All Green functions of the interacting system will then flow as a function of \( \Lambda \), and the true theory is recovered in the limit \( \Lambda \to 0 \). Salmhofer [8] has recently pointed out that (amputated) Green functions obtained by expanding the effective action of the theory in powers of normal ordered monomials of fermion fields obey differential flow equations with a structure that is particularly convenient for a power counting analysis to arbitrary loop order. With the bare interaction as initial condition at the highest scale \( \Lambda_0 = \max|\mathbf{k} - \mu| \), these flow equations determine the exact flow of the effective interactions as \( \Lambda \) sweeps over the entire Brillouin zone down to the Fermi surface. The effective low-energy theory can thus be computed directly from the microscopic model without introducing any ad hoc parameters.

For a weak coupling stability analysis it is sufficient to truncate the exact hierarchy of flow equations at 1-loop level. The effective 2-particle interaction then reduces to the one-particle irreducible 2-particle vertex \( \Gamma^\Lambda \), and its flow is determined exclusively by \( \Gamma^\Lambda \) itself (no higher many-particle interactions enter). Flow equations for susceptibilities are obtained by considering the exact RG equations in the presence of suitable external fields, which leads to an additional 1-particle term in the bare interaction, and expanding everything in powers of the external fields to sufficiently high order [3].

One cannot solve the flow equations with the full energy and momentum dependence of the vertex function, since \( \Gamma^\Lambda \) has three independent energy and momentum variables. The problem can however be much simplified by ignoring dependences which are irrelevant in the low energy limit, namely the energy dependence and the momentum dependence normal to the Fermi surface (for details, see Ref. [1]). This approximation is exact for the bare Hubbard vertex, and asymptotically exact in the low-energy regime. The remaining tangential momentum dependence is discretized for a numerical evaluation. Most of our results where obtained for a discretization with 16 points on the Fermi surface (yielding 880 "running couplings"), and we have checked that increasing the number of points does not change our results too much.

We have computed the vertex function for many different model parameters \( t' \) and \( U \) (\( t \) just fixes the absolute energy scale) and densities close to half-filling. In all cases the vertex function develops a strong momentum dependence for small \( \Lambda \) with divergences for several momenta at some critical scale \( \Lambda_c > 0 \), which vanishes exponentially for \( U \to 0 \). To see which physical instability is associated with the diverging vertex function we have computed commensurate and incommensurate spin susceptibilities \( \chi_S(\mathbf{q}) \) with \( \mathbf{q} = (\pi, \pi) \), \( \mathbf{q} = (\pi - \delta, \pi) \) and \( \mathbf{q} = (1 - \delta)(\pi, \pi) \), where \( \delta \) is a function of density [1]. The commensurate charge susceptibility \( \chi_C(\pi, \pi) \) and singlet pair susceptibilities with form factors [3]

\[
d(k) = \begin{cases} 
1 & (s\text{-wave}) \\
\frac{1}{\sqrt{2}}(\cos k_x + \cos k_y) & (\text{extended s-wave}) \\
\frac{1}{\sqrt{2}}(\cos k_x - \cos k_y) & (d\text{-wave } d_{2-\gamma}^x) \\
\sin k_x \sin k_y & (d\text{-wave } d_{xy})
\end{cases}
\]

Some of these susceptibilities diverge together with the vertex function at the scale \( \Lambda_c \). Depending on the choice of \( U \), \( t' \) and \( \mu \), the strongest divergence is found for the commensurate or incommensurate spin susceptibility or for the pair susceptibility with \( d_{2-\gamma}^x \) symmetry. In Fig. 1 we show a typical result for the flow of susceptibilities as a function of \( \Lambda \). Note the threshold at \( \Lambda \approx 0.03t \) below which the amplitudes for various scattering processes, especially umklapp scattering, renormalize only very slowly. The flow of the antiferromagnetic spin susceptibility is cut off at the same scale. The pairing susceptibility with \( d_{2-\gamma}^x \)-symmetry is obviously dominant here (note the logarithmic scale). Following the flow of the susceptibilities one can see that the \( d_{2-\gamma}^x \)-pairing correlations develop in the presence of pronounced but short-range antiferromagnetic spin-correlations, in agreement with earlier ideas on d-wave superconductivity in the Hubbard model [2].

In Fig. 2 we show the \((\mu, U)\) phase diagram for \( t' = -0.01t \) obtained by identifying the dominant instability from the flow for many different values of \( \mu \) and \( U \). For \( \mu = 4t' \) the Fermi surface touches the saddle points \((0, \pi)\) and \((\pi, 0)\), while \( \mu = 4t' + 0.01t \) corresponds to half-filling. Note that for \( U \to 0 \) the pairing instability always dominates, because the BCS channel dominates the flow in the limit \( \Lambda \to 0 \). A spin density wave is the leading instability for \( U \to 0 \) only in the special case with perfect nesting, \( t' = 0 \) and \( \mu = 0 \) (see the \((\mu, U)\) phase diagram computed from the 1-loop flow for \( t' = 0 \) in Ref. [1]).
How the critical energy scale \( \Lambda_c \) varies as a function of the chemical potential \( \mu \) for \( U = 1.5t \) and \( t' = -0.01t \). The different symbols indicate whether the leading instability is a spin-density wave or \( d \)-wave pairing instability.

Previous investigations of Fermi surface deformations within standard perturbation theory have yielded only very small shifts even for sizable interaction strengths \([12]\), but in these studies the possibility of a spontaneous breaking of the point group symmetry of the square lattice has not been taken into account.

To analyze systematically the stability of the Fermi surface shape, we define a susceptibility

\[
\kappa_{k_F,k'_F} = \frac{\delta s_{k_F}}{\delta \mu_{k'_F}}
\]  

which measures the size of Fermi surface shifts \( \delta s_{k_F} \) for small momentum dependent shifts of the chemical potential \( \delta \mu_{k'_F} \) at points \( k'_F \) on the Fermi surface. The matrix \( \kappa_{k_F,k'_F} \) defines a linear integral operator acting on functions of \( k_F \). A simple consideration in the spirit of phenomenological Fermi liquid theory shows that the corresponding inverse operator is given by

\[
(\kappa^{-1})_{k_F,k'_F} = v_{k_F} \delta (k_F - k'_F) + 2f^c_{k_F,k'_F}
\]

where \( v_{k_F} \) is the Fermi velocity and \( f^c_{k_F,k'_F} \) is the Landau function in the charge (spin-symmetric) channel. It is now obvious that the matrix \( \kappa_{k_F,k'_F} \) is symmetric. The Fermi surface is stable, if all eigenvalues of \( \kappa \) (or \( \kappa^{-1} \)) are positive. Note that Landau’s energy functional can be written as a quadratic form in \( \delta s_{k_F} \) with \( \delta \mu_{k'_F} \), with \( \kappa^{-1} \) as kernel \([13]\), and negative eigenvalues would imply that this energy can be lowered by a suitable deformation of the Fermi surface. In isotropic Fermi liquids such instabilities occur for strongly negative Landau parameters, as first pointed out by Pomeranchuk \([10]\).

We have computed the renormalization group flow of the eigenvalues and eigenvectors of the operator \( \kappa^{-1} \) from the flow of the Landau function \( f^c_{k_F,k'_F} \), which is given directly by the vertex function in the forward scattering channel \([14]\). For various choices of the model parameters we have always found a Fermi surface instability at a scale \( \Lambda_{sc}^f \) above the scale \( \Lambda_c \) where the vertex function diverges. In all cases the instability favors a deformation of the Fermi surface which breaks the point group symmetry of the square lattice, as shown schematically in Fig. 4. The instability is mainly driven by a strong attractive interaction between particles (or holes) on opposite
corners of the Fermi surface near the saddle points and a repulsive interaction between particles on neighboring corners.

The above diagnosis of Pomeranchuk instabilities would be rigorous for a normal Fermi liquid with finite renormalized interactions in the infrared limit. In the present system, however, the vertex function diverges at a finite scale and possible Pomeranchuk type instabilities compete with magnetic and superconducting instabilities. Since we have no quantitative theory of the strong coupling physics near and below the scale $\Lambda$, we can only list and discuss two possible scenarios:

i) Energy gaps due to particle-particle or particle-hole binding may stop the flow of forward scattering interactions before a Pomeranchuk instability sets in.

ii) The Pomeranchuk instability is not blocked by binding phenomena. In that case one would have a finite temperature phase transition with a spontaneous breaking of the (discrete) tetragonal symmetry of the square lattice, and subsequent continuous symmetry breaking associated with magnetic order or superconductivity in the ground state.

Which of the two scenarios is realized depends on the choice of the model parameters. The Pomeranchuk instability occurs more easily if the Fermi surface is close to the saddle points in the absence of perfect nesting. The best candidate is therefore the Hubbard model with a sizable $t'$ (reducing nesting) and $\mu = \epsilon_{cH}$.

We emphasize that the Pomeranchuk instability does not cut off the singularity in the Cooper channel since it does not break the reflection invariance. Hence, at sufficiently large doping away from half-filling, $d$-wave superconductivity will set in in any case, with an order parameter that may be slightly distorted away from perfect $d$-wave symmetry. The Pomeranchuk instability would also not destroy the umklapp scattering route to an insulating spin liquid discussed recently by Furukawa et al. [15].

To our knowledge a Pomeranchuk instability has not yet been observed in numerical solutions of the two-dimensional Hubbard model. Of course this may be due to finite size limitations or too high temperatures in Monte Carlo simulations. It would thus be interesting to compute the Fermi surface susceptibility $\kappa_{k_F}$ numerically.

In real systems a Pomeranchuk instability as in Fig. 4 may lead to an orthorhombic lattice distortion, as a consequence of the coupling of electronic and lattice degrees of freedom. High temperature superconductors indeed exhibit structural phase transitions between tetragonal and orthorhombic phases. It would be interesting to clarify whether a Pomeranchuk instability might drive (at least to a significant extent) the transition into the orthorhombic phase in these materials.

In summary, we have shown that modern renormalization group methods can be used to establish the expected $d$-wave pairing instability in the two-dimensional Hubbard beyond doubt. Note that for small bare interactions and in a parameter regime where only particle-particle pairing fluctuations grow strong, the strong coupling problem associated with the formation of a superconducting state can be treated rigorously [10]. Furthermore, we have pointed out that a Pomeranchuk instability breaking the tetragonal symmetry of the Fermi surface is likely to occur for a suitable choice of the model parameters, especially for a Fermi surface close to the saddle points in the absence of perfect nesting.
