Abstract. Recently, the idea of biogas production has become a popular topic in Poland. Biogas is a valuable source of renewable energy with a potential application in electricity and heat production. Numerous types of technological solutions of biogas production are closely linked to the availability of substrates in the area, as well as their quantity and their properties. The paper presents the assessment of application in biogas production selected wastes such as communal and household sewage sludge and waste from a paper production in Opole region (Poland). The annual productions of methane, biogas and electricity were estimated. Chosen physico-chemical properties important in fermentation process were taken into consideration in the assessment. The highest value of potential energy was obtained using waste from the paper industry but the most appropriate parameters for this process has sewage sludge from the municipal sewage treatment plant. The use of sewage sludge from domestic and municipal sewage and waste from the paper industry creates the opportunity to reduce the amount of waste materials.

1 Introduction

In Poland, the production of biogas derived from waste materials gains in popularity and the number of biogas plants is rising [1-3]. In 2016, in Poland, the register of the President of the Agricultural Market Agency (ARR) included 94 agricultural biogas installations on the list of biogas manufacturers. Their total installed electrical capacity was equal to 101,234 MW (this means a 21% increase in relation to 2015) [4].

The methane fermentation in a biogas plant involves biogas production through a process involving four phases (hydrolysis, acidogenesis, acetogenesis and methanogenesis) [5] on the basis of resources with various volume ratios of hydrocarbons, lipids and proteins [6-7]. The composition of such biogas is different depending on the applied substrates, however, typically it consists mostly of CH4 (40-70%) and CO2 (15-60%) as well as other compounds in small amounts: H2O (2-7%), N2 (2-5%), O2 (0-2%) < 1% H2, NH3 (0-1%) and H2S (0.005–2%) [5, 8-11]). The principal sources of biomass include: agricultural waste, communal solid waste, sewage sludge, forestry waste as well as industrial and animal remains, etc. [12]. According to [13] another interesting solution suitable for biogas production from waste is digestion of poultry manure or litter.

Agriculture forms the principal source of biodegradable waste. On the basis of data as of 2016, the ratios of the resources applied in the production of agricultural biogas are as follows [4]:

- distillery stillage 14.81%,
- maize silage 13.62%,
- beet pulp 6.89%,
- sludge from food and agricultural industry 3.88%,
- sludge obtained from dairy production 2.76%,
- sewage 2.67%,
- green forage 1.76%,
- other 8.93%.

These resources were applied in the production of 250 million m³ of biogas in 2016 (i.e. an increase of 21% in relation to 2015). In total, the production of electricity derived from agricultural biogas was equal to 524.6 GWh [4]. Nevertheless, the production of biogas in an anaerobic digestion is small in relation to the available technical potential [14].

The production of biogas is an important option in managing the existing wastes, as this process applies organic matter, which is difficult in application by other methods. In addition, biogas plants can aid in the utilization of waste produced in a given area, as the waste can be used locally.

Sludge from communal wastewater treatment plants and domestic treatment plants form one group of waste whose application can be potentially problematic. Although communal sludge obtained in wastewater treatment plants has been considered to be an adequate substrate for the production of biogas in large wastewater treatment plants for a long time, some areas, such as Opole province face a problem associated with its utilization.

Communal sewage sludge forms a considerable hazard to the environment due to its large volume and the
chemical composition.
In the last years, the dynamic development of domestic sewage treatment plants has led to a considerable increase in the volume of waste being produced in such facilities. On the basis of data obtained from the Central Statistical Office [15,16], the number of domestic sewage treatment plants increased from 181,000 in 2014 to around 203,000 in 2015.

The majorities, i.e. almost 85% of wastewater treatment facilities applied in individual households are located in rural areas (around 84% of underground containers without drainage systems and 92% of domestic sewage treatment plants). The variability of the physico-chemical properties of waste from domestic sewage treatment plants leads to the refusal to accept this type of waste by the communal wastewater plants due to the potential destabilizing effect of this waste in the normal treatment process. Hence, other measures are sought to further process this type of waste.

Waste obtained from the paper industry forms another group of waste posing a problem with its utilization. A large volume of waste in the form biomass originates from the processes in the cellulose and paper industry and its storage poses a hazard to the environment. The problems are associated with the high moisture content in this type waste, which is coupled with the large volume and variability in its composition. The methods applied to process this waste are too expensive and in some cases their impact on the environment can be problematic. In 2011, the overall production of this waste was equal to 932,900 tons, and in 2013, the production and processing of cellulose mass, paper and cardboard produced 1,085,000 tons of waste [19].

The objective of this paper is to assess the potential for the use of substrates formed by waste derived from communal and household sewage treatment plant and waste from a paper production plant applied in the production of biogas. The use of these substrates in the methane fermentation process could lead to the solution of a problem associated with the utilization of waste in the area of the Opole province (Poland).

2 Materials and methods

2.1 Substrates

The assessment of the properties that are important in the context of the application in biogas production involved a study involving four types of waste derived from facilities located in the Opole province. The sludge that was identified for the study came from two domestic sewage treatment plants (DSS I, DSS II), sewage sludge from a communal wastewater treatment plant (SS) and post-processing waste from paper production (PW).

The assessment of the properties of sludge obtained from domestic wastewater treatment applied from two facilities. The first of them is a domestic sewage treatment plant comprising a dual biological zone with a fluidized bed. This facility consists of an initial settling tank and two independent zones applied for an aerobic conditioning and a secondary tank. This plant is installed as an onsite facility for a single-family house occupied by a family of four and has been constantly applied for a period of 4 years. The other sewage treatment plant applied in the research comprises a two-chamber tank coupled with a drainage system. A single family of three uses this facility. It has been in use for 5 years.

Another type of the waste used in this study was formed by communal sewage sludge originating from a mechanical-biological wastewater treatment plant capable of increased treatment of biogens (WWTP). This plant was designed for a load of 225,000 population equivalent (PE) of waste, i.e. 45,000 m³ per day. The annual volume of waste conditioned by the plant is equal to around 96,966,000 m³ per year (including 12% of wastewater from industry) [18]. The sewage sludge samples were extracted from waste mixing chamber (i.e. sludge was obtained from the compactors that were dehydrated in the compactor and the initial settling tank). The post-processing waste from the paper industry made up the third type of the waste. The waste samples were extracted following the dehydration process (i.e. the composition of the waste was 40% dry mass) from the prisms where it is stored prior to its treatment or disposal.

2.2 Analysis methods

The sewage sludge and the waste from the paper industry were extracted and analyzed in accordance with the standards in force. The analysis involved the list of the following indicators:

- water content in accordance with PN-EN 12880:2004,
- pH in accordance with PN-EN 12176:2004,
- dry mass in accordance with PN-EN 12879:2004,
- total phosphorus in accordance with PN-EN 13346:2002, PN-EN ISO 11885:2009,
- total Kjeldahl nitrogen in accordance with PN-EN 13342:2002,
- ammoniacal nitrogen, in accordance with PN-575/0-34576/15,
- heavy metal concentration: Cd, Cr, Cu, Ni, Pb, Zn, in accordance with PN-EN 13346:2002, PN-EN ISO 11885:2009 and Hg in accordance with PN-EN 13346:2002, PN-EN 1483:2007,
- magnesium in accordance with PN-EN 13346:2002, PN-EN ISO 11885:2009,
- total organic carbon (TOC) in accordance with PB/FCH/17/ B:10.04. 2013.

3 Results and discussion

The analysis was initiated by assessing the total volume of the production of the waste in the area of the Opole province as well as in Poland with the purpose of determining the potential for biogas production from the waste.

The rough calculations were performed on the basis of the following relations:

- methane production (MP) [19]
The waste from the paper industry (PW) has the greatest potential for biogas production. This is due to the amount of the waste generated both locally and on the national scale. The potential for biogas production of the waste originating from the communal wastewater treatment plant and domestic sewage plants can give the production of 8,699.45 MWh/year of electricity on the national scale and 24,130 MWh/year on the scale of the Opole province. If we were to use all available waste for biogas production, we can reduce its amount by 75,214 tons per year on the scale of the Opole province. If we were to use all available waste for biogas production, we can reduce its amount by 2,109,194 tons per year on the national scale and by 950,290.22 m³ per year on the scale of the Opole province.

We need to note that the waste applied in the methane fermentation must be characterized by adequate properties. The results of the analysis involving physico-chemical properties of the waste are presented in Table 2 and the data is compared with the results with regard to the most common substrates used in biogas production. One of the parameters having a considerable impact on the course of the methane fermentation, and in particular on the stability of the process is associated with the maintenance of waste is pH. The optimum value of pH should be in the range from 6.5 - 8.0, which guarantees the beneficial environment for the growth of anaerobic bacteria [26]. An increase of pH above 8.5 makes the environment toxic for them [27-28]. The examined waste had a pH values that were slightly acid, (DSS I, DSS II, SS), and even neutral one (PW).

The waste from the paper industry demonstrates the lowest content of organic substances (31.3% d.m.). This value is also two times lower from the water content in both the domestic sewage plant and communal wastewater treatment plants. The study did not also establish considerable differences between the properties of the sludge from various domestic sewage treatment plants. The total phosphorus concentration is marginally present in the analyzed waste. In the sludge from WWTP the concentration of phosphorus is at a level of 1.81% d.m., whereas for DSS I and DSS II the values are equal to 0.586% d.m. and 0.504% d.m., respectively (i.e. a

The waste applied in the treatment plant and domestic sewage plants can give the production of 1033690.29 m³/year of biogas, 1.722,817.15 m³/m³ of waste. The study did not also establish considerable differences between the properties of the sludge from various domestic sewage treatment plants.
The content of the total phosphorus in the waste from the paper industry is lower in comparison to the remaining results (i.e. over 10 times lower in relation to the sludge from the domestic sewage treatment plants (DSS I and II), and 31 times lower in comparison to the sludge from the communal wastewater treatment plant (in comparison to the result recorded for maize silage). The sludge from the domestic sewage treatment plant (DSS I) had 5 times greater content of the organic carbon (a difference of 4.9 % d.m.) as compared to the sludge from the waste from the paper industry (10 % d.m.) and was characterized by the smallest concentration of the total nitrogen (0.47 % d.m.) among the analyzed waste.

Another important condition, which affects the activity of the bacteria, is the content of the total phosphorus in the substrate. It is necessary to achieve an adequate content of phosphorus (C:N:P) of 100:3:1 to ensure their optimum growth and to guarantee a high efficiency of CH4 production. In order to ensure that the anaerobic fermentation is performed in the conditions of an optimum C:N ratio, the biodegradable material should demonstrate a high C:N ratio [25,31]. The insights from the literature offer various ranges of the C:N ratio to achieve the adequate course of the methane fermentation process. Abbasi et al. [32] give that this ratio should be 20-30 :1, whereas the work [24,33] describes an experiment conducted in the conditions when the C:N ratio was 15-30:1. However, these authors found that microorganisms should have a ration of C:N 20-30:1 to ensure their optimum growth [24,31]. Another range of the C:N that was found to be optimum for the composition of the input for biogas production is equal to 10-25:1. The ratio of C:N in the waste, including DSS I, DSS II, PW, cattle slurry and cattle manure was adequate in this respect, whereas for SS it was equal to 7.9:1, which is far below the optimum value for the anaerobic process. For the case when the C:N ratio is too low (i.e. <10:1), nitrogen is released in the form of ammonia, and this leads to the increase of the environment pH [25].

Another important condition, which affects the course of biogas production, is associated with the heavy metal content in the waste. It is necessary to reduce the amount of heavy metals in the substrates to a minimum by applying a process of selection of substrates used in the fermentation process. However, not all metals have a negative impact on this process. The growth of microorganisms requires an adequate content of magnesium and trace elements such as copper and zinc [34]. The content of magnesium has a particular impact on the growth rate of microorganisms and this impact is similar

| Parameter       | Unit | Waste          | Cattle slurry [25,26] | Cattle manure [25-27] | Maize silage [26,28] |
|-----------------|------|----------------|----------------------|----------------------|----------------------|
| Water content   | %    | DSS I | DSS II | SS | PW | 88.0–95.0 | 67.0–87.0 | -         | -         |
| pH              | -    | 6.8   | 6.2   | 6.3 | 7.0 | -         | 7.7     | -         | -         |

to the role of basic nutrients. While the moderate concentrations stimulate the growth of the bacteria, excessive concentrations reduce this growth and even greater can play a considerably inhibitory effect on the process and even lead to toxicity [35]. The content of magnesium in the range from 1000 to 1500 mg/l can have a moderately slowing effect, whereas the range starting from 3000 mg/l can stop the growth of microorganisms altogether [36]. The content of Mg in the analyzed waste was only marginal, as we recorded 0.12-1.3 mg/kg d.m.

The waste applied for the testing has a various content of heavy metals. From the analysis of heavy metals, we learned that DSS I and II have a low content of heavy metals, just as for the case reported with regard to another domestic sewage treatment plant [37]. Such small volumes should not considerably affect the fermentation process. Heavy metals can occur in higher concentrations in communal waste and sludge [38, 39,40]. The diversity of the substrates, bacteria strains and environmental factors offer the explanation to the variability of the heavy metal concentrations, as well as their relative toxicity [35,41]. The inhibitory effect accompanied by the reduction of the production of biogas was reported for the cases when: Cu-40mg/l, Ni-10mg/l, Cd -70mg/l, Pb -340mg/l, Zn -400mg/l, Cr 3+-50mg/l, Cr 6+-1.10mg/l [36]. The concentration of heavy metals in the waste from the paper industry is similar to the result gained for the cattle manure, yet with a note that the latter contains more Cu. The tested waste, have a greater Zn concentration (614-1161 mg/kg d.m.) compared to the cattle slurry, cattle manure and maize silage (15.1-270 mg/kg d.m.). Among all analyzed types of waste, we learned that DSS I, DSS II, SS and PW were characterized by the highest values of Cu concentration (76.4-360 mg/kg d.m.). The concentration of Cr in DSS II (21.10 mg/kg d.m.) and SS (48.20 mg/kg d.m.) was higher in comparison to other types of waste (0.50-12.90 mg/kg d.m.). In addition, SS had a considerable level of Ni content (18.90 mg/kg d.m.).

4 Conclusions

Poland is a country with a considerable potential for biogas production, which can be applied in the methane fermentation process, among others based on waste. This process can involve the use of a wide range of organic waste, which is considered as noxious waste in terms of its utilization potential.

The examined waste is characterized by a considerable potential for use in biogas production. In particular, it can be applied jointly in co-fermentation with other substrates. It can form a cheap and easily accessible substrate for the production of biogas in the facilities that are already in operation.

The tested sewage sludge derived from domestic sewage treatment plants and a communal wastewater treatment plant demonstrates adequate physico-chemical properties for this purpose. This in particular refers to the adequate content of organic parts, TOC and nitrogen concentration. In addition, the concentration of heavy metals was low, which suggests that the amount available in the substrate should not have a negative impact on the fermentation process.

The application of sewage sludge in the production of biogas obtained from domestic sewage treatment plants, communal wastewater treatment plants and waste from the paper industry can offer an opportunity to solve the existing problem associated with utilization of this type of waste in the Opole province. The use of biogas for energy production can have a positive effect on the overall condition of the environment as well on the energy balance on the scale of the domestic economy. A considerable advantage associated with the use of selected substrates is associated with their accessibility, low cost of acquiring it and providing a solution to its utilization.
