Abstract. At the heart of causal structure learning from observational data lies a deceivingly simple question: given two statistically dependent random variables, which one has a causal effect on the other? This is impossible to answer using statistical dependence testing alone and requires that we make additional assumptions. We propose several fast and simple criteria for distinguishing cause and effect in pairs of discrete or continuous random variables. The intuition behind them is that predicting the effect variable using the cause variable should be ‘simpler’ than the reverse – different notions of ‘simplicity’ giving rise to different criteria. We demonstrate the accuracy of the criteria on synthetic data generated under a broad family of causal mechanisms and types of noise.

Keywords: Causal Structure Learning · Causality · Causal Direction · Information Theory · Minimum Description Length · Decision Trees

1 Introduction

Recent advancements in machine learning have enabled the efficient training of powerful statistical models from large amounts of high-dimensional data. Yet, despite their many successes, learning systems are still almost exclusively operating on the level of statistical associations among the observed variables [13].

The next big step in the field will involve causal inference; moving beyond simply capturing statistical associations to modelling cause and effect relationships among the underlying variables. Fields like healthcare & epidemiology [5, 19], bioinformatics & pharmaceutical research [10, 23, 18, 1], policy-making in social sciences [11, 16], energy & climate [3, 7], economics & finance [8, 20] and the physical sciences [22] will be among the first to benefit from the coming advancements in causal modelling.

The first challenge to reasoning about cause and effect lies in the construction of a causal model of the variables involved in a given problem. Learning the underlying causal structure from observational data –i.e. without performing a
randomized experiment is a challenging problem as it practically entails leaping from correlation to causation.

This work demonstrates that such a leap can be justified – under some assumptions – by using a simple intuition: predicting the effect variable using the cause variable (i.e. respecting the true causal direction) should be ‘simpler’ than the inverse. Different definitions of ‘simplicity’ yield different criteria for distinguishing cause from effect. We present a number of such criteria all of which are easy to implement, fast and applicable to both discrete & continuous random variables (r.v.’s). We demonstrate their accuracy on synthetic data generated under a broad family of causal mechanisms and types of noise.

2 Background

2.1 Causal Structure Learning & the 2-variable Problem

Let $X_i, i = 1, \ldots, n$ be r.v.’s, the causal relationships among which are captured by a Structural Causal Model (SCM) \cite{SCM1, SCM2} with an underlying causal graph $G$, a Directed Acyclic Graph, the vertices of which correspond to the random variables $X_i$ and an edge $X_i \rightarrow X_j$ denotes that $X_i$ has a direct causal effect on $X_j$.

The SCM models each $X_i$ as the result of an assignment,

$$X_i := f_i(\text{PA}_i, U_i), \quad i = 1, \ldots, n,$$

where $f_i$ is a deterministic function of $X_i$’s parents in $G$ (denoted by $\text{PA}_i$) and $U_i$ a stochastic unexplained variable (i.e. a noise variable). The set of noises $U_i, i = 1, \ldots, n$ are assumed to be jointly independent.

Causal structure learning, –i.e. inferring the underlying graph $G$– from observational data is a non-trivial problem. Observational data can inform us of statistical (in)dependences among variables but, this alone is not sufficient for uncovering the underlying causal graph. The reason is that a single independence relationship involving a set of variables can correspond to several underlying subgraph structures involving them.

The most characteristic example is determining the causal direction in the case of two random variables $X, Y$ that are statistically dependent. The Common Cause Principle \cite{CCP} captures the connection between causality and statistical dependence. It states that if two observables $X$ and $Y$ are statistically dependent, then there exists a variable $Z$ that causally influences both and explains all the dependence in the sense of making them independent when conditioned on $Z$. As a special case, this variable can coincide with $X$ or $Y$. In other words, the causal structures $X \rightarrow Y$, $Y \rightarrow X$ and $X \leftarrow Z \rightarrow Y$ are all consistent with observing the statistical dependence $X \not\perp Y$.

\footnote{If $\exists U_i \not\perp U_j, i \neq j$, then by the Common Cause Principle (see below), there exists another variable that explains their dependence and $G$ is thus not causally sufficient.}
2.2 Causal Direction, Complexity & Minimum Description Length

Does this mean that inferring causal direction from observational data is impossible? Not if we make additional assumptions. More concretely, let us assume we observe a statistical dependence $X \not\perp \perp Y$ and want to determine whether the causal direction is $X \rightarrow Y$ or $Y \rightarrow X^4$. It would be reasonable\textsuperscript{5} to assume that the true causal direction is the one that is the least complex to model.

Complexity can be interpreted in several ways, but ultimately the central argument is a general application of the Minimum Description Length (MDL) Principle\textsuperscript{6} which views learning as data compression: Learning to predict effect from cause should be simpler than the other way round amounts to the dataset being easier to compress when modelled in the causal direction \textsuperscript{9,15}.

Consider the (lossless) two-stage code that encodes a variable $Y$ with length

$L(Y)$ by first encoding a hypothesis $f_{X \rightarrow Y}$ (modelling $Y$ as a function of $X$) in the set of considered hypotheses $F$ and then coding $Y$ “with the help of” $f_{X \rightarrow Y}$: in the simplest context this just means “encoding the deviations of $Y$ in the data from the predictions made by $f_{X \rightarrow Y}$”. The description length of $Y$ is then:

$$L(Y) = \min_{f_{X \rightarrow Y} \in F} \{ L(f_{X \rightarrow Y}) + L(Y|f_{X \rightarrow Y}) \}. \quad (2)$$

Similarly, encoding $X$ with the aid of $Y$ (i.e. “encoding the deviations of $X$ in the data from the predictions made by $f_{Y \rightarrow X}$) we get:

$$L(X) = \min_{f_{Y \rightarrow X} \in F} \{ L(f_{Y \rightarrow X}) + L(X|f_{Y \rightarrow X}) \}. \quad (3)$$

Specifying a “language” for measuring the description length $L$ in practice (this is where our notion of complexity comes into play), we can reason that the true causal direction is $Y \rightarrow X$, if $L(Y) < L(X)$ or $X \rightarrow Y$, if $L(Y) > L(X)$. If $L(Y) = L(X)$, we do not have enough information to decide \textsuperscript{21,2}.

3 Simple Criteria for Distinguishing Cause & Effect

Using the framework described above, we will now present simple criteria for determining causal direction between two r.v.’s $X$ and $Y$. The goal is to compare the complexity of a model that uses as input $X$ to predict $Y$, denoted as $f_{X \rightarrow Y}$ against that of model that uses as input $Y$ to predict $X$, denoted as $f_{Y \rightarrow X}$.

For such a comparison to be meaningful, both models need to be drawn from the same model family $F$, e.g. by being generated by the same learning algorithm and hyperparameter configuration. For the purposes of this work, we opted for using Decision Trees of unbounded depth due to their ease of implementation and plethora of ways of characterizing their complexity. The criteria $J_{RE}$ &

\textsuperscript{4} We shall exclude from consideration the case of their dependence is a result of pure chance or that it is due to a third variable $Z$ s. t. $X \leftarrow Z \rightarrow Y$.
\textsuperscript{5} Philosophically, the intuition that the true causal mechanism is the simplest among all possible ones can be justified by the Occam’s Razor Principle.
are not limited to this specific modelling choice. The rest, are measures of complexity specific to decision trees and must be appropriately replaced should $f_{X \rightarrow Y}$ & $f_{Y \rightarrow X}$ be drawn from an alternative model family\(^6\).

Continuous data must be discretized so that both $X$ & $Y$ have the same cardinality (i.e. if both are continuous, we can use equal width binning.

For any criterion $J$, the rule for deciding causal directionality is the same:

\[
If \begin{cases} J > 0 \text{, then predict } X \rightarrow Y \\ J < 0 \text{, then predict } Y \rightarrow X \\ J = 0 \text{, then abstain from prediction} \end{cases}
\]  

\[J_{TD} = \text{Depth}(f_{X \rightarrow Y}) - \text{Depth}(f_{Y \rightarrow X}) \]  

\[J_{TN} = \text{Number of Nodes}(f_{X \rightarrow Y}) - \text{Number of Nodes}(f_{Y \rightarrow X}) \]  

\[J_{TL} = \text{Number of Leaves}(f_{X \rightarrow Y}) - \text{Number of Leaves}(f_{Y \rightarrow X}) \]  

\[J_{PL} = \text{Mean Path Length}(f_{X \rightarrow Y}) - \text{Mean Path Length}(f_{Y \rightarrow X}) \]  

\[J_{RE} = [H(Y) - H(Y - f_{X \rightarrow Y}(X))] - [H(X) - H(X - f_{Y \rightarrow X}(Y))] \]  

\(^6\) E.g. if the models are obtained via polynomial regression, the degree of the resulting polynomial or the number of its coefficients are naive measures of complexity.

\(^7\) For comparison, the depth of the tree corresponds to the maximal path length.
Interpolation Hardness Another approach is to directly compare the ability of \( f_{X \rightarrow Y} \) and \( f_{Y \rightarrow X} \) to fit the training data, i.e. to be used to predict the target. 

\[ J_{IH} = \text{Loss}(Y, f_{X \rightarrow Y}(X)) - \text{Loss}(X, f_{Y \rightarrow X}(Y)), \]  

where \( \text{Loss} \) denotes some appropriate loss function, e.g. for discrete r.v.’s, the misclassification error or for continuous r.v.’s the Mean Squared Error (MSE).

4 Empirical Evaluation

We generate 1000 datasets, each consisting of 1000 \((X, Y)\) pairs under the SCM:

\[
X = U_X \quad \quad Y = f_Y(X, U_Y),
\]

where \( U_X \) and \( U_Y \) are independent noise variables that can be either:

1. Discrete (resulting in discrete \( X \) & \( Y \)), in which case either can be:
   - a. Uniform, drawn from \( U(-R/2, R/2+1) \), \( R \) being the r.v.’s cardinality.
   - b. Discretized Gaussian, drawn from \( \mathcal{N}(0, 1) \), then discretized to \( R \) bins.
2. Continuous (resulting in continuous \( X \) & \( Y \)), in which case either can be:
   - a. Uniform, drawn from \( U(-1, 1) \).
   - b. Gaussian, drawn from \( \mathcal{N}(0, 1) \).

And \( f_Y \) is a deterministic function that can be \( f_Y(X, U_Y) = f_X^N(X) + f_Y^N(U_Y) \) or \( f_Y(X, U_Y) = f_X^N(X) \ast f_Y^N(U_Y) \) (additive or multiplicative noise), with both \( f_X^N \) and \( f_Y^N \) being polynomials of degree \( \in [1, 5] \) whose coefficients are integers \( \in [-10, 10] \). Both the degree and the coefficients are drawn uniformly from their respective sets. The causal direction is flipped with probability 0.5.

For each dataset, we calculate the value of each of the proposed criteria and predict the causal direction based on it. Continuous r.v.’s are discretized to 100 equal width bins. Tables 1 & 2 show the mean accuracy of each criterion across datasets, its accuracy ignoring cases in which it abstains, the mean value of the criterion for the causal and for the anti-causal direction. Figures 1 & 2 show the distribution of the values of each criterion for the causal and anti-causal direction. The dashed black line demarcates the decision threshold. Due to space limitations, we only present some of the results.

On discrete pairs of \( X \) & \( Y \), all criteria are very accurate, regardless of the distributions of the noise variables. Increasing the entropy of the cause r.v. (e.g. by increasing its cardinality \( R \)), only slightly decreases accuracy, but not considerably. Increasing the entropy of the effect r.v. (e.g. by increasing the cardinality \( R \) of its underlying noise variable) increases accuracy to 1. For, continuous \( X \), \( Y \), criteria based on tree depth (\( J_{TD}, J_{PL} \)) behave poorly (still above chance at predicting causal direction). Criteria based on tree width (\( J_{TN}, J_{TL} \)) must be flipped - i.e. modelling effect using cause is associated with larger tree width;

\[ 8 \text{ All code can be found at: } \url{https://github.com/nnikolaou/CausalDirectionality}. \]
Once this is done, they perform as accurately as in the discrete case. Criteria based on residuals ($J_{RE}, J_{IH}$) are very accurate. The above hold regardless of the noise distribution. Interestingly, when the noise is multiplicative the accuracy is higher – almost perfect for all criteria.

Table 1: Results of criteria on discrete $X$ & $Y$, under additive noise. Noise r.v.’s are both uniform with $R = 20$. $J_{RE}$ is normalized by target r.v.’s entropy.

| Criterion | $J_{TD}$ | $J_{TN}$ | $J_{TL}$ | $J_{PL}$ | $J_{RE}$ | $J_{IH}$ |
|-----------|----------|----------|----------|----------|----------|----------|
| Accuracy  | 0.988    | 0.986    | 0.986    | 0.989    | 0.974    | 0.986    |
| Accuracy when not Abstaining | 0.995 | 0.998 | 0.998 | 0.996 | 0.986 | 0.998 |
| Average value Causal | 9.252 | 39.000 | 20.000 | 6.883 | 0.214 | 0.865 |
| Average value Anti-causal | 37.417 | 437.215 | 219.107 | 16.864 | 0.819 | 0.118 |

Table 2: Results of criteria on continuous $X$ & $Y$, under additive noise. Noise r.v.’s are both uniform. $J_{RE}$ is normalized by target r.v.’s entropy.

| Criterion | $J_{TD}$ | $J_{TN}$ | $J_{TL}$ | $J_{PL}$ | $J_{RE}$ | $J_{IH}$ |
|-----------|----------|----------|----------|----------|----------|----------|
| Accuracy  | 0.583    | 0.909    | 0.909    | 0.628    | 0.976    | 0.990    |
| Accuracy when not Abstaining | 0.665 | 0.998 | 0.997 | 0.631 | 0.978 | 0.997 |
| Average value Causal | 12.871 | 198.766 | 99.883 | 8.905 | 0.024 | 0.920 | 0.909 |
| Average value Anti-causal | 14.314 | 188.454 | 94.727 | 9.251 | 0.113 | 427.146 |

5 Conclusion & Future Work

We demonstrated that inferring causal direction from observational data is possible, if we make the –justified by Occam’s Razor– assumption that predicting the effect using the cause should be simpler than the other way round.

We used decision trees to compare the difficulty of modelling $X$ using $Y$ vs. $Y$ using $X$. The resulting criteria we proposed address simplicity via the trees’ structure, the entropy of their outputs or the quality of their fit. They are
simple to implement, fast to compute and capable of handling both discrete and continuous variables. They were found to be highly accurate on a broad class of underlying causal mechanisms and noise types.

The results suggest that there are important differences between discrete and continuous features. For instance the modelling direction producing the tree of larger width tends to coincide with the true causal direction in the case of continuous variables and the anti-causal one for discrete r.v.’s. This suggests that width—in the case of continuous r.v.’s—captures aspects of fitting, not of redundant complexity and will be explored further.

A more detailed theoretical analysis and unified treatment of the criteria presented in this paper is left for an extended version of this work. So is its application to scenarios involving more than two variables, mixed (discrete & continuous) r.v.’s, a richer set of underlying causal mechanisms and applications to real world data.
Fig. 2: Scores of each criterion on continuous r.v.’s under additive noise; noise variables follow uniform distributions – see Fig. (1) for more details.
