ABSTRACT - Content-based image retrieval (CBIR) is a method for searching that finds related images in a medical database. Furthermore, a clinical adaptation of CBIR is hampered in part by a contextual gap that is the disparity among the person characterization of the picture and the framework characterization of the image. This technique makes it tough for the user to validate the fetched images that are similar to the query image in addition to that it only fetches the images of top-ranked and ignores the low-ranking ones. Visual Analytics for Medical Image Retrieval is a novel procedure for medicinal CBIR proposed in this research (VAMIR). By integrating human and machine analysis, Visual Analytics provides the potential to address the above-mentioned significant challenges. The texture properties are retrieved using the shape features extraction and Gray Level Co-occurrence Matrix (GLCM) is performed by contour-based shape descriptor. Using the Euclidean distance correlation metric, related medical pictures will be fetched by distinguishing the query image's attribute vector with the database images' respective attribute vectors. A vector of multiple features outperforms a vector of a single feature in terms of quality. The VAMIR implementation demonstrates that the search outcome for the user is acquired with 90% of recall and precision.

Keywords: Image retrieval, Lung CT images, Visual Analytics for Medical Image Retrieval (VAMIR), Content-based image retrieval.

1. INTRODUCTION

The action of collecting knowledge resources appropriate to a demand for knowledge from a repository of knowledge resources is known as information retrieval (IR). Entire content or further forms of content-based indexing could be used for searches. Information retrieval is the ability to retrieve relevant in a document and also look for metadata to characterize facts and datasets of pictures, sounds, or texts. While a person inserts a query into the model, the information retrieval procedure starts. Queries, like seek terms in web crawlers, be explicit representations of knowledge requests. The query cannot peculiarly identify a specific object in a group when it appears to retrieve information. Instead, numerous items might correspond to the query, with varying degrees of significance.

A computational framework for finding and obtaining images through a huge set of visual pictures is meant as a system of image retrieval. Digital images in the medical industry expand by thousands daily, posing some s retrieval, storage, and interpretation issues. In recent times, retrieving stored images from these huge archives for utilization in the clinical appliance, teaching, and research has been a key focus of medical informatics research [1]. CBIR has been employed for this rationale.

CBIR is a strategy for searching employed to find images that are related toward the query image [2] which is meant as content-based visual information retrieval (CBVIR) and query by image content (QBIC). The phrase “content” refers to shapes, colors, and textures. One of the key issues in the medical industry in current times has been the retrieval of images. CBIR, furthermore recognized as Content-based Medical Image Retrieval (CBMIR), is employed for this purpose [3]. The primary issue in CBIR is the discrepancy, which is the disparity between the system and human descriptions of an image. Several models are integrated through CBIR, however, it overlooks the images of low-ranked that are related to the query image. The CBIR model employs machine learning methods for feature selection and extraction to minimize the semantic gap.

Figure 1: CBIR framework
As illustrated within Fig.1, a user provides enters the system of retrieval framework in the form of an image. Then, for each of the query images and the database images, image features are extracted. The retrieval technique uses correlation measures to determine the correlation between the database images and query images [4]. The value of the similarity metric is ordered in descending format. Only the images with a high-rank value are taken into account which is highly correlated to the query image.

2. RELATED WORK

In the literature, Ashnil Kumar et al., (2015) the image is provided by the user as an input to the model. Images are used to extract features, which are then used in the selection process. The Pearson correlation coefficient approach is used in Automatic Feature Selection. The manually Selection procedure employs domain expertise and experience. The correlation between the database and query images is computed after feature selection. This method lets users include features that are relevant to them where the user is unaware of the retrieval algorithm.

Weidong Cai et al., (2000) provided a prototype concept for a dynamical positron emission tomography database system of content-based retrieval of the functional image. TTAC is a preprocessing input in a functional image analysis engine. Using the Knowledge-based cluster assessment approach, the image database engine extracts characteristics from the TTAC curve. The Euclidean distance approach is employed in a dynamic image archive framework to compare the attributes of database and query images. Converting from PTAC to TTAC might consume time but it can readily hold a bigger quantity of patient data.

Mahmudur Rahman et al., (2007) created a system comprised of both unsupervised and supervised learning approaches to minimize the conceptual gap and improve retrieval results. For extracting features, principal component analysis is performed. For classification and pre-filtering support vector machine (SVM) and fuzzy c-mean clustering methods are utilized. As a similarity comparison method, the statistical distance measure computes the similarity between database and query images. RF technology is utilized to do re-ranking, parameter updates, and query shifting all at the same time. Recall and precision results show that once the portion of categorized feedback records available is sparse, the SVM-based RF method performs poorly.

Gwenole Quellec et al., (2010) proposed a system for retrieving partial medical cases with contextual information. This approach is used on datasets from mammography screening (DDSM) and diabetic retinopathy follow-up (DRD). Mages are defined in this context as digital material. For the generation of decision trees, the C4.5 classification method is employed. The signatures’ distances and image signature are determined using Kullback–Leibler divergence and wavelet coefficient distribution. Clustering with a Fuzzy c-mean approach is used to cluster the signature. An AdaBoost method is employed to improve the accuracy of predicting by combining weak classifiers. Precision is utilized to compute the retrieval result's accuracy. Boosting does not result in a statistically meaningful gain in accuracy over the full dataset.

3. PROPOSED SYSTEM
To address the semantic gap, incorporate visual analytics into the Medical CBIR approach known as Visual Analytics for Medical Image Retrieval (VAMIR). During a channeled search among the huge attribute set employing the query image as a reference position, VAMIR would allow more efficient and effective retrieval and inference of current medical images. VAMIR will also be able to assess ‘missed’ images from other approaches.

The system depicted in Figure 2 includes a CBIR engine, representations for the query image, images obtained, in addition to VA modules that enable the person to strain and choose images and their characteristics for investigation. In our approach, no single CBIR engine is needed, and alternative engines can be employed for various databases or scenarios. The VAMIR modules in the process provide an intuitive graphical strategy for analyzing CBIR engine retrieval outcomes. Principles for visualization and search interfaces recommend that various differing opinions of data that are complex, explorations to comprehend it, the demonstration of auxiliary data, in addition to the potential to converse by the visualization to modify the data provided otherwise to tweak the subspace can facilitate appropriate human perception of visualized information.

Following parameters and our ultimate goal of employing VA to investigate the extracted features, VAMIR is created. The prerequisites comprise the subsequent:

1) Supplying alternative perspectives on the attributes gap.
2) Facilitating automated attribute choice depending on person input to colonize all of the points of view.
3) Avoiding the depiction of numerous huge images by extrapolating the separate images at every view.
4) Enabling direct image examination by integrating each conceptualization into its related image.
5) Permitting the person to filter the visualization
6) Facilitating the person to filter otherwise transform the seek-out gap and fine-tune the query with dynamism.

3.1 VAMIR visualization design

Our visualization approach is based on the idea that just a fraction of the figure characteristics are necessary for a person to comprehend the obtained outputs related towards the query, that is, a fragment of the attributes has top importance for a similar image. [5]. Based on the query, the user, or the concluding retrieval appliance, the subset may transform. Hence, by clustering images according to their correlation using the subset of features, the VAMIR visualization lets the user notice significant patterns that are not visible in a ranking. The nodes of usage (points) in the visualization of VAMIR serve as abstractions of images. If the variance between the feature subset of two nodes is minimal, then merge them. Interacting using visualization lets users peek in on specific areas of relevance and study the relationship between population dynamics throughout the connected feature clusters [6]. Users may subsequently use domain expertise about the significance of image attributes, such as tumor volume, to proactively change and optimize the query or investigate other subsets of features.

3.2 VAMIR analytics interactions

3.2.1 Image Visualization

Whereas the VAMIR process gives additional imminent keen on image correlation, a user must still inspect the real figure to determine the complete qualities of an instance (e.g., stages of infection). To determine whether an image obtained by feature space exploration meets the supplied search purpose, a connection between both the conceptual representation and the real image is provided [8].

3.2.2 Node Selection

The proposed visualization is built on solitary feature pairs, allowing persons to investigate the significance of certain attributes to image correlation. To permit the user to contrast images utilizing various groupings of characteristics, a global selection scheme [9] is employed. It connects the nodes from every sector as well as the super-Centre. When a user chooses nodes inside one area, they simultaneously choose the matching nodes in every subsequent sector and the super-Centre. By selecting numerous nodes in a single sector, the user may determine to suppose imagery be grouped close to any form in entire attribute pairs (relatively highly correlated) else merely part of it (an outlier).

3.2.3 Dynamic Querying

If an initial query was an outlier in comparison, the person might discover it beneficial to narrow it by employing an image in the dataset where the node is near to such query node inside a specific region. VAMIR subsequently receives the dataset's correlation to an incoming query from the CBIR framework. This correlated data is utilized to immediately revive the display while maintaining the attribute couplings [10]. After that, the modules depicting the query and the visuals obtained have been modified.

4. DATASETS USED

The image repository of the Lung Image Database Consortium (LIDC-IDRI) comprises diagnostic and screening thoracic computed tomography (CT) images through highlighted interpreted tumors. This records assortment includes 1018 instances and is produced in association with 7 academia and 8 imaging medical firms. Every context holds imagery commencing a medical thoracic CT scan plus an XML document with the outcomes of a 2 stage image analysis process completed via 4 experienced thoracic radiologists. During the first completely blinded stage, every radiologist separately assessed every CT scan moreover classified laceration into 1 of 3 groups ("non-nodule > or =3 mm", "nodule <3 mm", and "nodule > or =3 mm"). Before reaching a final decision, every radiologist independently reviewed the markings, and also the anonymous markings of the 3 additional radiologists, within the phase of unblended-read.
Table 1: Database description

| COLLECTION STATISTICS | COUNTS AND DEPICTION |
|------------------------|-----------------------|
| Modalities             |                       |
| CR(computed radiography)|                       |
| DX(digital radiography)|                       |
| CT(computed tomography)|                       |
| Count of patients      | 1,010                 |
| Count of radiologists  | 4                     |
| Nodule size comparison | nodule>=3,            |
|                        | nodule<3,             |
|                        | non-nodule            |
| Count of Images        | 244,527               |
| Image Size (GB)        | 124                   |

5. IMPLEMENTATION

5.1 Feature extraction

The feature gives relevant information about the images. Feature extraction is the most critical step because it signifies the move from graphical data description to non-pictorial data description. The resulting representation can be used as an input to further processing image processing. Shape and texture are the two most commonly employed attributes in medical image retrieval. Texture attributes provide information on the spatial configuration of color, a particular part of an image, and intensity levels in an image.

5.1.1 Texture feature extraction

As shown in Fig.3 Texture is described as an abstraction made up of pixels that are connected and a collection of pixels. It is classified into two approaches as Structural Approach, Statistical Approach [11]. Here, a statistical approach is used for retrieving texture characteristics.

5.1.2 Gray Level Co-occurrence matrix (GLCM)

Table.1, it is the tabulation of how often the different combination of pixel grey levels co-occurs in an image. It is the foremost traditional second-order statistical approach for analyzing texture. Second-ordered notes relationship between groups of two pixels in the original image.

Algorithm Steps

Step 1: Convert the image in color into an image in grayscale.
Step 2: Grayscale image is transformed into matrix format based on the gray level in the images.
Step 3: Construct the GLCM Matrix by counting the co-occurrence of pixels in the original image matrix
Step 4: Find Transpose of a GLCM matrix by interchanging the row and columns of the matrix.
Step 5: Add the original matrix to its transpose.
Step 6: Normalize the GLCM Matrix by using the Eq.(1)

\[ P_{ij} = \frac{V_{i,j}}{\sum_{i=0}^{N-1} \sum_{j=0}^{N-1} V_{i,j}} \]  

5.1.3 Shape feature extraction

The form of an item, as seen in Figure 4, alludes to its intrinsic structure. The border, region, moment, and so on may all be used to depict the form. These visualizations could be employed to match shapes, recognize objects, and measure shapes. Contour-based shape descriptor used for Shape features extraction. Different kinds of shape attributes are constructed for object identification, and their accuracy in retrieving comparable shapes from a database is measured. Accurate form descriptors must be able to successfully discover comparable shapes from the database for excellent retrieval. A shape descriptor must be able to get images for a wide range of forms rather than just a few, and it should be application agnostic. Here, a contour-based shape descriptor is used for Shape features extraction.

5.1.4 Contour-based shape descriptor

Boundary information will be retrieved employing contour-based approaches. For extraction of features, information such as circularity, area, minimum length, maximum length, and so on are determined via the boundary parameters. Because simple shape characteristics may only distinguish between objects with considerable variances, they are frequently coupled with various shape attributes for an effective retrieval procedure. (Figure 5)
5.2 Feature selection

It signifies the task of deciding on a division of the retrieved characteristics. It will be known as an attribute or inconsistent selection [12]. The precision of the outcomes may be affected by the features used. By deleting unnecessary and redundant features, it picks the finest division of the attributes among the real retrieved attribute.

**Regression:** It is the statistical method for modeling the relationship between the variables. It starts with no independent variables. It adds the variable one at a time as long as a significant reduction in the error sum of squares (SSE) can be achieved. In the simple regression model, split the features into a dependent variable and independent variables. The dependent variable is the single variable being predicted by the regression model [13]. The Independent variable is the explanatory variable used to predict the dependent variable.

**Dependent variable:** Correlation

**Independent variables:** Inverse Difference Moment, Information Measure of Correlation II, Contrast, Variance, Energy, Sum Entropy, Entropy, Difference Entropy, Sum Average, Sum Variance, Difference Variance, Information Measure of Correlation I, Maximal Correlation Coefficient.

5.3 Query image selection and feature extraction

As exposed in Figure 6 and 7, the user picks the query image from the test image dataset. The Query image attributes are obtained using GLCM Matrix which is used in dataset feature extraction.

5.4 Similarity matching technique

This is certainly solitary among the most important concerns in CBIR. It has to be chosen to determine by what means similar one vector is to some other. Finding effective correlation metrics across images depending upon characteristic sets is a difficult problem. This was a technique for evaluating the difference/correlation among database and query images [14]. The distance equations vector can be used to calculate similarity.

**Euclidean distance:** As shown in Figure 8 and 9, as shown in Equation (2), the correlation-based result is obtained by calculating the Euclidean distance amid the image in the database and the query image.

\[
d(q, r) = \sqrt{\sum_{j=1}^{n} (f_{j}(q) - f_{j}(r))^2}
\]

- \(q\) represents an image of query,
- \(r\) represents an image of reference \(i\) from the database of reference,
- \(f\) represents a \(j^{th}\) feature,
- \(n\) represents feature spaces’ dimensionality.
5.4 Visual analytics approach

As shown in Figure 10 and 11, this technique permits the user to add attributes that are deemed important [15]. The person is unrequired to be aware of the algorithm utilized for retrieval. This allows persons to discover visuals by investigating the complete dataset by identifying the certain visuals overlooked by the correlation matching method.

5.6 Performance measures

CBIR models are evaluated based on effectiveness and efficiency. Efficiency is determined by the rate of restoration and efficacy employing the increased significance of the restoration. Frequently employed CBIR As shown in Figure 12, performance measures are obtained by precision and recall [17] by Equations (3) & (4). Precision is described as the proportion of images retrieved that are most relevant to the overall number of database images [16]. The recall is calculated by dividing the count of relevant images retrieved by the overall numeral of appropriate database images.

\[
\text{precision} = \frac{\text{Number of relevant images retrieved}}{\text{Number of images retrieved}} \tag{3}
\]

\[
\text{Recall} = \frac{\text{Number of relevant images retrieved}}{\text{Number of relevant images in the dataset}} \tag{4}
\]

Z-Score Normalization

As shown in Figure 13, Z-Score normalization means rescaling the feature X by deducting the average \( \mu \) and dividing via its standard deviation \( \sigma \) as given in Equations (5),

\[
z - \text{score} = \frac{(X - \mu)}{\sigma} \tag{5}
\]
6. CONCLUSION & FUTURE ENHANCEMENT

In this work, a novel framework is depicted for medical CBIR known as Visual Analytics for Medical Image Retrieval (VAMIR). This approach offers the opportunity to solve the above complex problems by combining human and automated analysis. VAMIR's capabilities reduce semantic gaps by allowing users who may not search algorithm experts to use the search process to explore the attribute space and discover images considered to be similar. Users could indeed find images that could have been missed otherwise significantly lowered rankings through techniques that employ the ranked listing by reviewing the complete dataset.

The visual quantitative method is better suited for multi-modality imaging and volumetric. This framework was only applicable to one clinical group. Our future research will focus on under what circumstances VAMIR could be utilized in various clinical groups of a user by incorporating domain-specific interactions and visualizations.
