Decentralized Data Reduction with Quantization Constraints

Ge Xu, Shengyu Zhu, Student Member, IEEE, and Biao Chen, Senior Member, IEEE

Abstract—A guiding principle for data reduction in statistical inference is the sufficiency principle. This paper extends the classical sufficiency principle to decentralized inference, i.e., data reduction needs to be achieved in a decentralized manner. We examine the notions of local and global sufficient statistics and the relationship between the two for decentralized inference under different observation models. We then consider the impact of quantization on decentralized data reduction which is often needed when communications among sensors are subject to finite capacity constraints. The central question we intend to ask is: if each node in a decentralized inference system has to summarize its data using a finite number of bits, is it still optimal to implement data reduction using global sufficient statistics prior to quantization? We show that the answer is negative using a simple example and proceed to identify conditions under which sufficiency based data reduction followed by quantization is indeed optimal. They include the well known case when the data at decentralized nodes are conditionally independent as well as a class of problems with conditionally dependent observations that admit conditional independence structure through the introduction of an appropriately chosen hidden variable.

Index Terms—Decentralized inference, sufficiency principle, sufficient statistic, quantization.

I. INTRODUCTION

A guiding principle for data reduction is the sufficiency principle [1]–[3]. A sufficient statistic is a function of the data, chosen so that it ‘should summarize the whole of the relevant information supplied by the sample’ [1]. A classical example is in binary hypothesis testing where the likelihood ratio can be shown to be a sufficient statistic of the unknown hypothesis, thus can be used instead of the raw data for subsequent decision making [4]. Another example is the waveform channel with additive white Gaussian channel as often assumed in digital communications [5]. It can be easily established that the outputs of simple correlators (or equivalently, that of matched filters) form a sufficient statistic for the unknown input signals. In both examples, the original data, often of high or infinite dimensions, is reduced to low dimension statistics which greatly facilitate the subsequent inference. Indeed, the sufficiency principle has played a prominent role in designing various data processing methods for statistical inference and it encompasses numerous results that have been developed since Fisher’s original work. The well-known Neyman-Fisher factorization theorem, for example, provides a systematic way for identifying sufficient statistics using the likelihood function.

This paper studies data reduction in decentralized inference and extends the sufficiency principle to systems where data reduction needs to be done locally. Decentralized inference refers to the decision making process involving multiple sensors [6]. Each sensor summarizes its observation and sends a message to the fusion center, which makes the final decision based on the messages it receives. Sensor processing is independent of each other as each sensor has access only to its own data. Illustrated in Fig. 1 is a two-sensor canonical model for decentralized inference where sensors are connected in parallel to a fusion center.

For decentralized inference, data reduction is done locally without access to the global data. Therefore, the contrasting notions of local sufficiency and global sufficiency need to be treated with care [7]. A sufficient statistic defined with respect to local data is referred to as a local sufficient statistic; if a collection of local statistics form a global sufficient statistic, they are said to be globally sufficient. For the special case when data are conditionally independent given the inference parameter, local sufficient statistics are known to be globally sufficient [7]–[9]. However, for the general case when data are conditionally dependent, a set of local sufficient statistics need not be globally sufficient and vice versa. The first objective of this paper is to develop theories and tools for decentralized data reduction with conditionally dependent observations for parallel networks. We show that global sufficiency of local statistics is not determined solely by the statistical characterization of local data but also depends on the statistical property of the global data.

Sufficiency based data reduction ensures no loss of inference performance using the reduced data. While the sufficiency principle often results in maximum dimensionality reduction, communicating a one-dimensional real data may still be infeasible when communication is subject to a finite capacity constraint. In this paper, we consider the simple case where each sensor node communicates only a finite number of bits to the fusion center, i.e., it needs to summarize its observation using a finite number of bits. Directly quantizing the raw data,
especially if the data is of high dimension and quantizers operate in a decentralized fashion, is often a formidable task \cite{10,11}. As such, it is often desirable to achieve maximum data reduction at each node prior to quantization.

We are then led to the question: is it optimal to implement data reduction by forming a collection of global sufficient statistics followed by the design of optimal quantizers using the reduced data? Alternatively, one can consider the sufficiency principle to be the ubiquitous principle for data reduction in a ‘lossless’ sense, that is, complete information in the original data needs to be retained in the statistics. When practical constraints such as finite-bit quantization are imposed which result in inevitable loss of information, is sufficient principle still the guiding principle for data reduction?

Unfortunately, as seen from Example 4, the answer to this question is negative in general. However, there exist known results where quantizing sufficient statistics is shown to be optimal. The classical example is distributed detection with conditionally independent observations where the local likelihood ratios form a set of global sufficient statistics. Indeed, Tsitsiklis established in \cite{12} that likelihood ratio quantizers (LRQ’s) are optimal for a broad class of performance criteria. There also exist instances where quantizing local sufficient statistics is globally optimal for certain parameter regimes in the dependent observation case \cite{13}. The second objective of this paper is thus to identify, for decentralized inference involving dependent data, conditions under which data reduction is still optimal when quantization is required at each node. While the result includes that of \cite{12} as its special case, the approach differs from that of \cite{12} as we do not start with an explicit form of quantizers thus can not explore the structural information of the statistics as that of \cite{12}. Instead, our approach utilizes the Markovian structure implied in sufficient statistics. On the other hand, our optimality is strictly in the sense of minimizing a Bayesian risk as opposed to that of \cite{12} which includes a broader class of performance criteria.

Preliminary results were reported in \cite{14} and \cite{15}. In addition to expanding on the technical details of previous studies, the current paper introduces an alternative characterization of structurally optimal data reduction (cf. Section IV- C).

Also related to the present work is the quantizer design for distributed estimation in \cite{10} and \cite{11} where necessary conditions for optimal quantizers are derived. The present work does not explicitly address the quantizer design problem. Instead, we derive sufficient conditions such that sufficient statistics based data reduction followed by quantization is structurally optimal. Various optimal quantizer design approaches can then be applied to the reduced data which is often much more tractable than dealing with the raw data.

The rest of the paper is organized as follows. Section II reviews the basic sufficiency principle for centralized inference, including the optimality of sufficient data reduction when quantization is required. Section III deals with data reduction in decentralized inference with conditionally dependent observations in the absence of a quantization constraint. In Section IV the sufficiency principle is re-examined in decentralized inference when quantization is necessary at each node, i.e., only a finite number of bits can be used to summarize the reduced data at each sensor. Both conditionally independent and conditionally dependent observations are considered. We establish the structural optimality of sufficiency based data reduction followed by quantizers for the independent case. For the dependent case, we identify a class of problems where we prove that sufficiency based data reduction is still optimal in the presence of quantizers. In Section V-C we obtain a sufficient condition under which the sufficiency based data reduction stills attains the same optimal inference as the raw data. It includes both the independence and dependence conditions as its special cases. Section VI concludes the paper.

II. CENTRALIZED INFERENCE

In this section, we consider a simple centralized inference system where the entire data is available at a single node. We review the basic sufficiency principle for centralized inference and then establish the optimality of sufficient data reduction when quantization is required.

A. Sufficiency principle

Suppose $\theta$ is the parameter of interest and $X \triangleq \{X_1, \cdots, X_n\}$ is a random vector observation collected at the node, whose distribution is given by $p(x|\theta)$. The sufficiency principle states that a function (or statistic) of $X$, denoted by $T(X)$, is a sufficient statistic for $\theta$ if the inference outcome does not change when either $x$ or $y$ is observed as long as $T(x) = T(y)$ \cite{2}. A useful tool to identify sufficient statistics is the Neyman-Fisher factorization theorem \cite{16} which states that a statistic $T(X)$ is sufficient for $\theta$ if and only if there exist functions $g(t|\theta)$ and $h(x)$ such that

$$p(x|\theta) = g(T(x)|\theta)h(x).$$  

(1)

If the parameter $\theta$ is itself random, the sufficiency principle can be elegantly reframed using the data processing inequality, assisted with the use of Shannon’s mutual information \cite{16}. That is, a function $T(X)$ is a sufficient statistic if and only if the following Markov chain holds

$$\theta \rightarrow T(X) \rightarrow X,$$

(2)

which is equivalent to the mutual information equation

$$I(\theta;X) = I(\theta, T(X)).$$

(3)

The following lemma, which is used throughout the paper, is a straightforward result from the definition of Markov chain.

**Lemma 1:** Let $X \sim p(x|\theta)$ where $\theta$ is a random parameter. If $T(X)$ is a sufficient statistic for $\theta$ with respect to $X$, then

$$p(\theta|x) = p(\theta|T(x)).$$

**Proof:** As $T(X)$ is a function of $X$, $\theta \rightarrow X \rightarrow T(X)$ form a Markov chain. Together with (2), we have

$$p(\theta|x) = p(\theta|x, T(x)) = p(\theta|T(x)).$$

1\ We do not distinguish between probability density and probability mass functions. Its meaning will become clear in the context of specific problems.
B. Centralized inference with quantization

Consider a centralized inference system in which quantization is required, as shown in Fig. 2(a). Here, \( \theta \) is the parameter of inference interest with distribution \( p(\theta) \). \( X \) is the random vector observation, \( \gamma(\cdot) \) is the quantizer directly operating on the data \( X \) and the output of the quantizer is \( U = \gamma(X) \in \{0, \ldots, L-1\} \) where \( L \) is the number of possible outputs. The estimator at the fusion center is denoted by the function \( h(\cdot) \) whose input is the quantizer output.

Let \( T(X) \) be any sufficient statistic for \( \theta \). To establish the optimality of sufficiency based data reduction with a quantization constraint, we need to investigate whether the two systems in Fig. 2 achieve the same optimal performance where the second system applies data reduction to obtain \( T(X) \) prior to a quantization operation. The quantizer and estimator in Fig. 2(b) are similarly defined by \( U' = \gamma'(T(X)) \) and \( h'(U') \). Note that for a centralized system there is no distinction between local and global sufficient statistics.

Let \( d[\theta, \hat{\theta}] \) be a given cost function between the parameter \( \theta \) and the estimator output \( \hat{\theta} \). For the model in Fig. 2(a) \( \hat{\theta} = h(U) = h(\gamma(X)) \). The Bayesian risk is the expected cost function given by

\[
R = E\{d[\theta, h(\gamma(X))]\}, \tag{4}
\]

where the expectation is taken with respect to both the random parameter \( \theta \) and the observation \( X \). For the model in Fig. 2(b) \( \hat{\theta}' = h'(\gamma'(T(X))) \) and the Bayesian risk is given by

\[
R' = E\{d[\theta, h'(\gamma'(T(X)))]\}, \tag{5}
\]

where again the expectation is taken with respect to \( \theta \) and \( X \). We now establish that the system described in Fig. 2(b) is structurally optimal, i.e., it can achieve the same inference performance as that of Fig. 2(a) hence quantizing the sufficient statistic achieves the same minimum Bayesian risk as quantizing the observation in centralized inference.

**Theorem 1:** For the Bayesian risks in (4) and (5),

\[
\min_{\gamma, h} R = \min_{\gamma', h'} R'.
\]

**Proof:** Let

\[
R_{\min} = \min_{\gamma, h} R.
\]

Denote by \( \gamma^*(\cdot) \) and \( h^*(\cdot) \) the optimal quantizer and estimator that achieve \( R_{\min} \) is achieved. Apparently, \( R' \geq R_{\min} \) as one can always define a new quantizer \( \gamma(X) = \gamma'(T(X)) \) for any given \( \gamma'(\cdot) \), thus converting any system described by Fig. 2(b) to that of Fig. 2(a) whose performance is no better than \( R_{\min} \).

Then we only need to show that there exist \( \gamma'(\cdot) \) and \( h'(\cdot) \) such that the corresponding \( R' = R_{\min} \).

Expanding \( R \) in (4) with respect to the observation \( X \), we have

\[
R = \int \int d[\theta, h(\gamma(x))] p(x, \theta) dx d\theta
= \int \int d[\theta, h(\gamma(x))] p(\theta|x) p(x) dx d\theta
\]

\[
= \int \int d[\theta, h(\gamma(x))] p(\theta|T(x)) p(x) dx d\theta
\]

\[
\triangleq \int \alpha(u, x) p(x) dx, \tag{6}
\]

where

\[
u \triangleq \gamma(x),
\]

\[
\alpha(u, x) \triangleq \int d[\theta, h(u)] p(\theta|T(x)) d\theta,
\]

and (a) is from Lemma 1 From (6), \( \gamma^*(\cdot) \) must be such that it chooses \( u \) to minimize \( \alpha(u, x) \) with \( h^*(\cdot) \) used as the estimator, that is

\[
U = \gamma^*(X) = \arg \min_u \alpha(u, X). \tag{7}
\]

Therefore, \( u = \gamma^*(x) = s \in \{0, \ldots, L-1\} \) given the observation \( x \) if for any \( t \in \{0, \ldots, L-1\} \),

\[
0 \geq \alpha(s, x) - \alpha(t, x)
\]

\[
= \int [d[\theta, h^*(s)] - d[\theta, h^*(t)]] p(\theta|T(x)) d\theta. \tag{8}
\]

Given \( h^*(\cdot), \) (8) is a necessary condition for \( \gamma^*(\cdot) \) to achieve \( R_{\min} \). Note that (8) depends on \( X \) only through \( T(X) \), hence can be realized by a \( \gamma'(T(X)) \). If we use this \( \gamma'(\cdot) \) together with \( h'(\cdot) = h^*(\cdot) \), then \( R' = R_{\min} \).

The above result is not surprising in view of the fact that a sufficient statistic captures all the information about \( \theta \) contained in the data. Indeed, the above theorem can be viewed as a simple instantiation of the sufficiency principle for the Bayesian risk. Other inference objective functions can also be used. Consider for example the “indirect rate distortion problem” where a noisy version of a source sequence is observed at the encoder while the decoder tries to minimize the end-to-end distortion subject to a rate constraint between the encoder and the decoder. It was shown in [18] that data reduction using a sufficient statistic at the encoder does not affect the rate distortion function.

In decentralized inference, however, the same statement is not necessarily true, i.e., sufficient statistics based data reduction may not be optimal when quantization is required at individual nodes. Before we study the impact of quantizers on data reduction in a decentralized system, we first revisit the sufficiency principle when no quantization is required. In particular, we strive for a better understanding of the relationship between local and global sufficient statistics under various dependent models.
III. SUFFICIENT STATISTICS IN DECENTRALIZED INFERENCE

This section considers the decentralized data reduction in a two-sensor parallel network as illustrated in Fig. 1. The results extend naturally to the case with an arbitrary number of sensors. Let \( \theta \sim p(\theta) \) be the parameter of interest and \( X_i \), the local observation at sensor \( i \) for \( i = 1, 2 \). For a decentralized system, there is a need to distinguish between the notions of local and global sufficient statistics. When \( \theta \) is random, for \( i = 1, 2 \), \( T_i(X_i) \) is a local sufficient statistic if

\[
\theta - T_i(X_i) - X_i
\]  

(9)

form a Markov chain, i.e., sufficiency is defined with respect to the local observation \( X_i \). On the other hand, we call \((T_1(X_1), T_2(X_2))\) a global sufficient statistic if

\[
\theta - (T_1(X_1), T_2(X_2)) - (X_1, X_2)
\]  

(10)

form a Markov chain. It is apparent that for the general case, the two individual Markov chains (9) and (10) do not imply each other.

A. Conditionally Independent Observations

For the conditional independence case, it can be easily established that local sufficiency implies global sufficiency. The converse also holds for the conditional independence case, which is given in the following proposition.

**Proposition 1:** Let \( X_1 \) and \( X_2 \) be conditionally independent observations given the random parameter \( \theta \). If \((T_1(X_1), T_2(X_2))\) form a global sufficient statistic for \( \theta \), then both \( T_1(X_1) \) and \( T_2(X_2) \) are locally sufficient statistics with respect to the observations \( X_1 \) and \( X_2 \).

We first state some useful properties of Markov chains that will be used for subsequent proofs:

- Symmetry: \( X - Z - Y \Rightarrow Y - Z - X \);
- Decomposition: \( X - Z - YW \Rightarrow X - Z - Y \);
- Weak Union: \( X - Z - YW \Rightarrow X - ZW - Y \);
- Contraction: \( X - Z - Y \) and \( X - ZY - W \Rightarrow X - Z - YW \);
- Intersection: \( X - ZW - Y \) and \( X - ZY - W \Rightarrow X - Z - YW \).

**Proof:** Since \( X_1 \) and \( X_2 \) are independent given \( \theta \), \( X_1 - \theta - X_2 \) form a Markov chain and so does \((X_1, T_1(X_1)) - \theta - X_2 \) as \( T_1(X_1) \) is a function of \( X_1 \). Using the weak union property, we have that \( X_1 - (\theta, T_1(X_1)) - X_2 \) form a Markov chain. That \((T_1(X_1), T_2(X_2))\) is globally sufficient implies that (10) holds and thus \( X_1 - (T_1(X_1), T_2(X_2)) - \theta \) form a Markov chain according to the decomposition and symmetry properties. Combining \( X_1 - (\theta, T_1(X_1)) - X_2 \) and \( X_1 - (T_1(X_1), T_2(X_2)) - \theta \), and using the intersection property we get the Markov chain \( X_1 - T_1(X_1) - (\theta, T_2(X_2)) \) whenever \( p(x_1, t_1(x_1), t_2(x_2), \theta) \) is positive. Thus \( T_1(X_1) \) is a local sufficient statistic for \( \theta \). That \( T_2(X_2) \) is locally sufficient for \( \theta \) can be established similarly.

B. Conditionally Dependent Observations

While the above establishes that global and local sufficient statistics imply each other for conditionally independent observations, the same is not true for the dependent case. Consider the following trivial example.

**Example 1:** Let \( X_1 = X_2 \) in Fig. 1. It is clear that \((T_1(X_1) = X_1, T_2(X_2) = \emptyset)\) is globally sufficient for \( \theta \) while \( T_2(X_2) = \emptyset \) is not locally sufficient.

The rest of this section is devoted to the question of how to identify global sufficient statistics at distributed nodes with conditionally dependent observations. Our approach leverages a recently proposed hierarchical conditional independence (HCI) model, which is a new framework developed for distributed detection with conditionally dependent observations. An HCI model is constructed by introducing a hidden variable \( W \) such that the following Markov chains hold:

\[
X_1 - W - X_2, \quad \theta - W - (X_1, X_2).
\]  

(11)

That is, \( W \) induces conditional independence between \( X_1 \) and \( X_2 \) as well as conditional independence between the inference parameter \( \theta \) and the sensor observations \((X_1, X_2)\).

It was established in [20] that any general distributed inference model is equivalent to an HCI model and vice versa. Notice here that while we only illustrate the HCI model using the two sensor system, the framework is applicable to that involving any arbitrary number of sensors where we replace the Markov chain \( X_1 - W - X_2 \) with the equivalent conditional independence assumption.

Notice that the second Markov chain in defining the HCI model implies that the information about the inference parameter \( \theta \) in the data \((X_1, X_2)\) is preserved entirely in \( W \). This is formalized in the following lemma.

**Lemma 2:** Let \( X_1, X_2 \sim p(x_1, x_2|\theta) \) and suppose that there exists a random variable \( W \) such that

\[
\theta - W - (X_1, X_2).
\]  

(12)

A statistic \( T(X_1, X_2) \) that is sufficient for \( W \) is also sufficient for \( \theta \).

**Proof:** The Markov chain (12) implies that \( \theta - W - (X_1, X_2, T(X_1, X_2)) \) forms a Markov chain for any statistics \( T(X_1, X_2) \). That \( T(X_1, X_2) \) is sufficient for \( W \) implies the Markov chain \( W - T(X_1, X_2) - (X_1, X_2) \). It is straightforward to show that these two Markov chains give rise to a long Markov chain

\[
\theta - W - T(X_1, X_2) - (X_1, X_2).
\]  

Therefore, \( T(X_1, X_2) \) is sufficient for \( \theta \).

**Lemma 2** is not useful in itself as \( T(X_1, X_2) \) is a function of the global data which is not available in either of the nodes. Its use is mainly for establishing the following result.

**Theorem 2:** Let \( X_1, X_2 \sim p(x_1, x_2|\theta) \) and suppose there exists a random variable \( W \) such that \( \theta - W - (X_1, X_2) \). Let \( T(W) \) be a sufficient statistic for \( \theta \), i.e., \( \theta - T(W) - W \).

1) If a pair of statistics \( (T_1(X_1), T_2(X_2)) \) are globally sufficient for \( T(W) \), they are globally sufficient for \( \theta \).

2) If \( T(W) \) induces conditional independence between \( X_1 \) and \( X_2 \) and \( (T_1(X), T_2(X_2)) \) are locally sufficient for
implies that local sufficient statistics are globally sufficient, obtain the Markov chain \( \theta \), the contraction property. Combined with the Markov chain result in 1) thus establishes that they are also sufficient for \( \theta, Z, U \). where \( \theta \) is chosen appropriately. For example,\( X_1, \cdots, X_K \) are locally sufficient for \( X \), and independent conditioned on \( \theta, \theta, \theta \), \( \rho \) and independent noises \( \epsilon_{1:m} \) in the presence of a fading assumption. Therefore, \( |S| \) serves as the hidden variable \( W \) for the HCI model corresponding to this decentralized hypothesis testing problem.

C. Examples

We now use a simple example to show how Corollary 1 can be used for data reduction through an appropriately chosen \( W \).

**Example 2:** For \( i = 1, \cdots, n \), let
\[
\begin{align*}
X_{1i} &= \theta + Z + U_i, \\
X_{2i} &= \theta + Z + V_i,
\end{align*}
\]
where \( \theta, Z, U_1, \cdots, U_n, V_1, \cdots, V_n \) are mutually independent Gaussian random variables such that \( \theta \sim \mathcal{N}(0,1) \), \( Z \sim \mathcal{N}(0, \rho) \), \( U_j \sim \mathcal{N}(0,1-\rho) \), \( V_i \sim \mathcal{N}(0,1-\rho) \). Thus, we need to estimate a parameter \( \theta \) in the presence of a constant interference \( Z \) and independent noises \( U_i \) and \( V_i \). Since \( X_{1i}, X_{2i} \sim \mathcal{N}(\theta, 1, 1, \rho) \), given \( \theta \) \( X_1 \) and \( X_2 \) are not independent conditioned on \( \theta \).

Choose the hidden variable \( W = \theta + Z \). One can verify easily that \( W \) satisfies the Markov chains \( \theta \rightarrow W \rightarrow (X_1, X_2) \) and \( X_1 \rightarrow W \rightarrow X_2 \) required by the HCI model. For Gaussian observations, it is also clear that \( \sum_i X_{1i} \) and \( \sum_i X_{2i} \) are locally sufficient for \( W \). Therefore, from Corollary 1 \( (\sum_i X_{1i}, \sum_i X_{2i}) \) is globally sufficient for \( \theta \).

While the above example is somewhat artificial, it does provide a clue for how to choose a meaningful hidden variable - often times, the signal model itself provides a natural choice of \( W \) as in Example 2. Specifically, the signal plus interference term \( \theta + Z \) satisfies both Markov chain conditions and turns out to be precisely the hidden variable that leads to meaningful data reduction. The next example is motivated by the cooperative spectrum sensing problem [21]. As with

Example 2, the choice of \( W \) can also be obtained by careful examination of the signal model.

**Example 3:** Consider the hypothesis testing problem involving \( K \) sensors with the two hypotheses under test given by
\[
H_1: X_k = h_k S + N_k, i = 0, 1,
\]
where \( X_k, k = 1, \cdots, K, \) is the observation at sensor \( k \), \( h_k \)’s are circularly symmetric complex Gaussian and independent of each other and of other variables, \( S \) is a signal taking values in \( S_0 = \{s_0 = 0\} \) under \( H_0 \) and \( S_1 = \{s_m = r_m e^{j\theta_m}, m = 1, \cdots, M\} \) with probability \( p(S = s_m) = \pi_m \) under \( H_1 \), and \( N_k \) is the observation noise at the \( k \)th sensor which is circularly complex Gaussian distributed and is independent of each other. This hypothesis testing problem can be used to describe the baseband model of detecting the presence of a QAM signal in independent Rayleigh fading channels using \( K \) sensors.

The observations are not conditionally independent under \( H_1 \) given that the observations contain a common random signal \( S \). Again, taking a Bayesian viewpoint where we assume that the true hypothesis \( H \) is a binary random variable, then \( H \rightarrow S \rightarrow (X_1, \cdots, X_K) \) form a Markov chain since the observations depend on the hypothesis only through the signal. It is easy to verify that the statistic \( |S| \) is sufficient for \( H \) given \( S \). Thus, the Markov chain \( H \rightarrow |S| \rightarrow S \rightarrow (X_1, \cdots, X_K) \) holds. On the other hand, given \( |S| \), the observations are conditionally independent of each other under the independent Rayleigh fading assumption. Therefore, \( |S| \) serves as the hidden variable \( W \) for the HCI model corresponding to this decentralized hypothesis testing problem.

For any \( k \), \( |X_k| \) is a minimal sufficient statistic for \( |S| \). This can be easily verified by writing out the ratio \( \frac{p(x_k|s)}{p(x_k'|s)} \) for two sample points \( x_k \) and \( x_k' \). Therefore, from Corollary 1 \( \{ |X_k| \}, k = 1, \cdots, K, \) are globally sufficient for \( H \).

IV. DECENTRALIZED DATA REDUCTION WITH QUANTIZATION CONSTRAINTS

We now consider decentralized inference where quantization is required at each node. For simplicity and ease of presentation, we again assume a simple two-node system, as illustrated in Fig. 3. The result extends to systems with more than two nodes in a straightforward manner.

Let \( \theta \sim p(\theta) \) be the parameter of interest and \( X_i \) the local observation at sensor \( i \) with a likelihood function \( p(x_i|\theta) \), for \( i = 1, 2 \). Statistics and quantizers at local nodes, as well as the estimator at the fusion center are defined in a similar fashion as in Section II. Let \( d(\theta, \hat{\theta}) \) be the cost function where \( \theta \) is the true parameter and \( \hat{\theta} \) its estimate. The Bayesian risks for the systems in Fig. 3(a) and Fig. 3(b) are given respectively by

\[
R = E\{d(\theta, h(U_1, U_2))\}
\]
and
\[
R' = E\{d(\theta, h'(U_1', U_2'))\},
\]
where \( U_i = \gamma_i(X_i) \in \{0, \ldots, L - 1\} \) and \( U_i' = \gamma_i'(T_i(X_i)) \in \{0, \ldots, L - 1\} \).

The additional constraint that a quantizer is used at each sensor node may lead to inevitable information loss. As such, it is not clear whether global sufficient statistics based data reduction is still optimal. That is, even if \( (T_1(X_1), T_2(X_2)) \) form a global sufficient statistic, can the system in Fig. 3(b) achieve the same performance as that of Fig. 3(a)?

The answer, unfortunately, is no, as can be seen from the following simple example.

**Example 4:** Consider the degenerate case where \( X_1 = X_2 \) and \( U_i \) is constrained to be of one bit. Clearly \( (T_1(X_1) = X_1, T_2(X_2) = \emptyset) \) is a global sufficient statistic. However it is trivial to see that quantizing such constructed \( T_1(X_1) \) and \( T_2(X_2) \) using 1-bit each can be suboptimal compared with quantizing the data directly, with the former equivalent to a 1-bit quantizer of the data whereas the latter a 2-bit quantizer. Specifically, for the latter case, \( X_1 \) and \( X_2 \) are quantized at each node thus provide more information to the fusion center.

An acute reader has probably realized that the above example involves data that are conditionally dependent given the parameter of interest. It turns out when data are conditionally independent given \( \theta \), the answer is indeed the affirmative, i.e., quantizing sufficient statistics is structurally optimal.

**A. Conditionally Independent Observations**

**Theorem 3:** For the Bayesian risks in (13) and (14) when \( X_1 \) and \( X_2 \) are conditionally independent given \( \theta \),

\[
\min_{\gamma_1, \gamma_2, h} R = \min_{\gamma_1', \gamma_2', h'} R'.
\]

Note that for conditionally independent observations, there is no need to distinguish between local and global sufficient statistics. We now establish Theorem 3 using the Bayesian risk for a two-sensor system.

**Proof:** Let

\[
R_{\min} = \min_{\gamma_1, \gamma_2, h} R,
\]

where the minimum Bayesian risk is achieved by the optimal quantizers \( \gamma_i^* \) and estimator \( h^*(\cdot) \). It is easy to see that Fig. 3(b) can not achieve a better performance than \( R_{\min} \) for any given \( T_i(\cdot) \) and \( \gamma_i'(\cdot) \), one can simply define \( \gamma_i(X_i) = \gamma_i'(T_i(X_i)) \) whose performance is bounded by \( R_{\min} \). Thus we only need to show that \( R_{\min} \) can be achieved by Fig. 3(b) i.e., one can find \( (\gamma_1^*(\cdot), \gamma_2^*(\cdot), h^*(\cdot)) \) that achieve \( R_{\min} \) for the given sufficient statistics \( T_1(X_1) \) and \( T_2(X_2) \). Similar to the proof for the centralized case, it suffices to show that the optimal quantizers \( \gamma_i^*(X_i) \) achieving \( R_{\min} \) depends on \( X_i \) only through \( T_i(X_i) \).

As \( X_1 \) and \( X_2 \) are conditionally independent,

\[
p(x_1, x_2, \theta) = p(\theta)p(x_1|\theta)p(x_2|\theta) = p(x_1)p(\theta|x_1)p(x_2|\theta) = p(x_1)p(\theta|T_1(x_1))p(x_2|\theta).
\]

The last step comes from the fact that \( T_1(X_1) \) is sufficient for the data \( X_1 \) and Lemma 1. Expanding \( R \) with respect to \( X_1 \), we get

\[
R = \int_{\theta} \int_{x_1} \int_{x_2} d[\theta, h(\gamma_1(x_1), \gamma_2(x_2))]p(x_1, x_2, \theta)dx_2dx_1d\theta
\]

\[
= \int_{\theta} \int_{x_1} \int_{x_2} d[\theta, h(\gamma_1(x_1), \gamma_2(x_2))]p(x_1)p(\theta|T_1(x_1))p(x_2|x_1)dx_2dx_1d\theta
\]

\[
\triangleq \int_{x_1} \alpha_1(u_1, x_1)p(x_1)dx_1,
\]

where

\[
\alpha_1(u_1, x_1) \triangleq \int_{x_2} \int_{\theta} d[\theta, h(u_1, u_2)]p(\theta|T_1(x_1))p(x_2|\theta)d\theta dx_2.
\]

Let \( \gamma_2(\cdot) \) and \( h(\cdot) \) take the form of the optimal \( \gamma_2^*(\cdot) \) and \( h^*(\cdot) \), \( \gamma_1^*(\cdot) \) must be chosen such that the corresponding \( \alpha_1(u_1, x_1) \) is minimized. The condition for making \( u_1 = \gamma_1^*(x_1) = s \in \{0, \ldots, L - 1\} \) given \( X_1 = x_1 \) is, for any \( t \in \{0, \ldots, L - 1\} \),

\[
0 \geq \alpha_1(s, x_1) - \alpha_1(t, x_1) = \int_{x_2} \int_{\theta} [d[\theta, h^*(s, \gamma_2^*(x_2))] - d[\theta, h^*(t, \gamma_2^*(x_2)))]p(\theta|T_1(x_1))p(x_2|\theta)d\theta dx_2,
\]

which depends on \( X_1 \) only through \( T_1(X_1) \).

The optimal quantizer \( \gamma_2^*(\cdot) \) at the second node, given that \( \gamma_1(\cdot) \) and \( h(\cdot) \) take the form of \( \gamma_1^*(\cdot) \) and \( h^*(\cdot) \), can be similarly shown to be a function of the sufficient statistic \( T_2(X_2) \). Thus we have established that both \( \gamma_1^*(\cdot) \) and \( \gamma_2^*(\cdot) \) can be equivalently expressed as functions of \( T_1(X_1) \) and \( T_2(X_2) \) respectively, i.e., there exist \( \gamma_1'(\cdot) \) and \( \gamma_2'(\cdot) \) such that

\[
\gamma_1'(T_1(X_1)) = \gamma_1^*(X_1),
\]

\[
\gamma_2'(T_2(X_2)) = \gamma_2^*(X_2).
\]

Therefore, the above \( \gamma_1'(\cdot) \) and \( \gamma_2'(\cdot) \), together with \( h'(\cdot) = h^*(\cdot) \), achieves \( R_{\min} \) for Fig. 3(b).

The fact that likelihood ratio quantizer is optimal for decentralized detection with conditionally independent observations can be naturally derived from the above general result.

**Example 5:** Let \( \theta \in \{0, 1\} \) and its estimate \( \hat{\theta} \in \{0, 1\} \). The observations \( X_1 \) and \( X_2 \) are independent given \( \theta \). Let \( d(\cdot) \) take the form of \( 0 - 1 \) cost, i.e., \( d[\theta, \hat{\theta}] = 0 \) when \( \theta = \hat{\theta} \) and 1 otherwise. It is a trivial exercise to show \( T_i(x_i) = p(x_i|\theta=0) \) is a sufficient statistic for \( \theta \) with respect to \( X_i \). Thus quantizing \( T_i(X_i) \) is structurally optimal, which is consistent.
with (12) as the inference problem is precisely a hypothesis testing problem.

B. Conditionally Dependent Observations

While the previous section establishes the optimality of sufficiency based data reduction for conditionally independent observations even with quantization constraints, Example [4] indicates that such is not the case with conditionally dependent observations. Nevertheless, in this section, we establish that within the problems involving dependent observations, there exist a class of problems such that quantizing sufficient statistics is still structurally optimal. Here we again utilize the HCI model [20].

Theorem 4: Let \( W \) be a hidden variable such that (11) is true. If \( T_1(X_1) \) and \( T_2(X_2) \) are local statistics that are sufficient with respect to \( W \), then quantizing \( T_1(X_1) \) and \( T_2(X_2) \) at the respective sensor is structurally optimal for the decentralized inference problem.

Proof: Let \( R_{\text{min}} \) be the minimum Bayesian risk achieved by Fig. 2(a) with the corresponding optimal quantizers \( \gamma^*_i(\cdot) \), and estimator \( h^*(\cdot) \). We show that \( \gamma^*_i(X_i) \) is necessarily a function of the sufficient statistic \( T_i(X_i) \).

Without loss of generality, we assume that \( W \) is continuous. From (11), we have

\[
p(x_1, x_2|\theta) = \int_W p(x_1, x_2, w|\theta) dw = \int_W p(x_1|w)p(x_2|w)p(w|\theta) dw = \int_W \frac{p(w|x_1)p(x_2|w)}{p(w)} p(w|\theta) dw = p(x_1) \int_W \frac{p(w|T_1(x_1))}{p(w)} p(x_2|w)p(w|\theta) dw.
\]

Expanding \( R \) with respect to \( X_1 \), we obtain

\[
R = \int_{x_1} \int_{x_2} \int_{\theta} d[\theta, h(\gamma_1(x_1), \gamma_2(x_2))p(x_1, x_2, \theta)dx_2dx_1d\theta = \int_{x_1} \int_{x_2} \int_{\theta} d[\theta, h(\gamma_1(x_1), \gamma_2(x_2))\frac{p(w|T_1(x_1))}{p(w)} p(w|\theta)] \times p(x_2|w)p(w|\theta) dw dx_2 dx_1 d\theta = \int_{x_1} \alpha'_1(u_1, x_1)p(x_1) dx_1,
\]

where

\[
\alpha'_1(u_1, x_1) \triangleq \int_{x_2} \int_{\theta} d[\theta, h(u_1, u_2)\frac{p(w|T_1(x_1))}{p(w)} p(w|y)] \times p(w|\theta) dw dx_2 d\theta.
\]

From (15), \( \gamma^*_1(X_1) \) depends on \( X_1 \) only through \( T_1(X_1) \). Similar argument shows that \( \gamma^*_2(\cdot) \) is also a function of the sufficient statistic \( T_2(X_2) \).

The key to applying the above result also depends largely on a well chosen \( W \) for the HCI model. As discussed in Section III-C, the choice of \( W \) can often be obtained by careful examination of the signal model. We now continue with Examples 2 and 3 by adding quantization constraints to the respective problems.

Example 6: Consider Example 2 under the quantization constraint, i.e., we need to estimate \( \theta \) based on the quantized version of \( X_1 \) and \( X_2 \). Since \( \sum_j X_{1j} \) and \( \sum_j X_{2j} \) are locally sufficient for the hidden variable \( W \), quantizing \( \sum_j X_{1j} \) and \( \sum_j X_{2j} \) is structurally optimal by Theorem 4.

Example 7: Consider Example 3 when quantization is needed at each node. In Example 3 we have shown that \( \{X_k\}, k = 1, \ldots, K \) are globally sufficient for \( H \). Therefore, from Theorem 4 quantizing \( \{X_k\} \) at the \( k \)th sensor is structurally optimal. This result is consistent with that in [21] which shows that the optimal detector at each local sensor is an energy detector for the corresponding cooperative spectrum sensing problem, i.e., in the form of a threshold test using \( |X_k|^2 \).

As a final technical note, the conditional independent case can be considered as a special case of Theorem 4. Specifically, setting \( W = \theta \), one can see that Theorem 3 follows naturally from Theorem 4.

C. An Alternative Condition for Structural Optimality

Theorems 3 and 4 established the structural optimality of sufficiency based data reduction with independent data and with dependent data under a given HCI structure, respectively. In this section, we provide an alternative characterization that encompasses both cases. To proceed, we note that in Theorems 3 and 4 the joint distribution \( p(x_1, x_2, \theta) \) can be expressed in both cases as the product of \( p(x_1) \) and a nonnegative function of \( T_1(x_1) \), \( x_2 \) and \( \theta \). We show that this factorization is indeed what is needed to establish that quantizing \( T_1(X_1) \) achieves the same optimal inference performance as quantizing \( X_1 \) given that the optimal quantizer \( \gamma^*_1(\cdot) \) and the optimal estimator \( h^*(\cdot) \) are used at the second sensor and at the fusion center respectively.

Theorem 5: If there exist two nonnegative functions \( g(\cdot) \) and \( h(\cdot) \) and a statistic \( T_1(X_1) \) such that

\[
p(x_1, x_2, \theta) = g(x_1)f(T_1(x_1), x_2, \theta),
\]

then quantizing \( T_1(X_1) \) achieves the same optimal inference performance as quantizing \( X_1 \).

From (19), if we marginalize \( X_2 \) on both sides, we have

\[
p(x_1, \theta) = g(x_1) \int_{x_2} f(T_1(x_1), x_2, \theta) dx_2.
\]

Thus, by the factorization theorem 2, (19) implies that \( T_1(X_1) \) is a local sufficient statistic for \( \theta \).

Proof: Let \( R_{\text{min}} \) be the minimum Bayesian risk achieved by Fig. 3(a) with quantizer \( \gamma^*_1(\cdot) \) and estimator \( h^*(\cdot) \). We show that, if (19) holds, then \( \gamma^*_1(X_1) \) depends on \( X_1 \) only through the sufficient statistic \( T_1(X_1) \).
Again, expanding $R$ with respect to $X_1$, we get
\[
R = \int \int \int d\theta, h(\gamma_1(x_1), \gamma_2(x_2))p(x_1, x_2, \theta)dx_2dx_1d\theta
\]
\[
= \int \int \int d\theta, h(\gamma_1(x_1), \gamma_2(x_2))g(x_1)f(T_1(x_1), x_2, \theta)
\times dx_2dx_1d\theta
\]
\[
\triangleq \int x_1 \alpha''(u_1, x_1)g(x_1)dx_1,
\]
where
\[
\alpha''(u_1, x_1) \triangleq \int \int d\theta, h(u_1, \gamma_2(x_2))f(T_1(x_1), x_2, \theta)
\times dx_2d\theta.
\]

Given the optimal second quantizer $\gamma_2^*(\cdot)$ and estimator $h^*(\cdot)$, $\gamma_1^*(\cdot)$ must be such that it minimizes $\alpha''(u_1, x_1)$, i.e., $u_1 = \gamma_1^*(x_1) = s \in \{0, \ldots, L - 1\}$ if for any $t \in \{0, \ldots, L - 1\}$,
\[
0 \geq \alpha''(s, x_1) - \alpha''(t, x_1).
\]
The proof is thus complete by recognizing that $\alpha''(u_1, x_1)$ depends on $x_1$ only through $T(x_1)$. ■

Theorem 5 provides an alternative way of formulating the sufficiency based data reduction, i.e., one may directly check the joint probability $p(x_1, x_2, \theta)$ instead of searching for a meaningful hidden variable $W$. While Theorem 5 appears to be more general than Theorem 4, we show in the following that these two theorems are indeed equivalent to each other in that they imply each other. This observation is also consistent with the fact that the conditional independence case can also be considered as a special case of the HCI model.

**Proposition 2**: Thereoms 4 and 5 are equivalent.

**Proof**: The direction that Theorem 5 implies Theorem 4 is trivial as [17] satisfies [19]. We now show the other direction. Notice that given [19], $\theta - (T_1(X_1), X_2) - (X_1, X_2)$ form a Markov chain and
\[
p(x_1, x_2) = \int \int p(x_1, x_2, \theta)d\theta
\]
\[
= \int g(x_1)f(T_1(x_1), x_2, \theta)d\theta
\]
\[
= g(x_1)\int f(T_1(x_1), x_2, \theta)d\theta,
\]
which shows that $X_1 - T_1(X_1) - X_2$ and hence $X_1 - (T_1(X_1), X_2) - X_2$ are two Markov chains. Combining $\theta - (T_1(X_1), X_2) - (X_1, X_2)$ and $X_1 - (T_1(X_1), X_2) - X_2$, we can choose $(T_1(X_1), X_2)$ as our hidden variable in the HCI model. That $X_1 - T_1(X_1) - X_2$ is a Markov chain also implies that $(T_1(X_1), X_2) - T_1(X_1) - X_1$ form a Markov chain. Then $T_1(X_1)$ is a sufficient statistic for $(T_1(X_1), X_2)$ with respect to $X_1$ and achieves the structural optimality by Theorem 4. ■

The fact that [19] implies that $T_1(X_1)$ is a sufficient statistic for $X_1$ does not mean $T_1(X_1)$ being a sufficient statistic is a necessary condition for optimality. This is because [19] itself is only a sufficient condition for optimality. Given below is a trivial example illustrating that a local statistic which achieves optimality is not necessarily a sufficient statistic.

Example 8: For $i = 1, \ldots, n$, let
\[
X_{1i} = \theta + W_i,
\]
\[
X_{2i} = \theta + V_i,
\]
where $\theta, W_1, \ldots, W_n, V_1, \ldots, V_n$ are mutually independent Gaussian random variables such that $\theta \sim \mathcal{N}(0,1)$, $W_j \sim \mathcal{N}(0,1)$, $V_j \sim \mathcal{N}(0,1)$. Then $X_1$ and $X_2$ are conditionally independent given $\theta$. It is also clear that $\sum_i X_{1i}$ and $\sum_i X_{2i}$ are locally sufficient for $\theta$, thus quantizing $\sum_i X_{1i}$ and $\sum_i X_{2i}$ can achieve the optimal inference with corresponding quantizers $\gamma_1^*(\cdot)$ and $\gamma_2^*(\cdot)$ and the optimal estimator $h^*(\cdot)$.

Now consider another local statistic $U(X_1) = \gamma_1^*(\sum_i X_{1i}) \in \{0, 1\}$. If we quantize this statistic instead of $\sum_i X_{1i}$ at the first node while using $\gamma_2^*(\cdot)$ at the second node and $h^*(\cdot)$ at the fusion center, the optimal inference is also guaranteed, although the corresponding quantize is for $U(X_1)$ is a degenerate one, i.e., an identity mapping. It is trivial to see that $U(X_1)$ is not a sufficient statistic for $\theta$. ■

V. CONCLUSION AND DISCUSSIONS

In this paper we have extended the sufficiency principle for decentralized data reduction with dependent observations where data reduction needs to be done locally at distributed sensors. For the conditional independence case, local sufficiency and global sufficiency imply each other. For the dependent observations, however, there is no definitive connection between the two notions of sufficiency in general. Using a recently proposed HCI model, we establish conditions under which local sufficiency implies global sufficiency with dependent observations.

A more interesting, and practically more important question is the study of decentralized data reduction when each sensor is subject to a quantization constraint. We do not address explicit quantizer design in this work; instead, we find sufficient conditions such that a separation approach, namely data reduction followed by a quantizer, is structurally optimal under the Bayesian inference framework for both centralized inference and decentralized inference with conditionally independent observations. For decentralized inference with conditionally dependent observations, quantizing sufficient statistics, even global ones, need not be optimal. Nevertheless, utilizing the HCI model, we have provided a suitable way of finding optimal data reduction if it exists.

While Theorem 4 helps identify cases where meaningful data reduction can be achieved for dependent observations, identifying suitable hidden variable $W$ often requires careful examination and a good insight into the signal model. An alternative, yet equivalent formulation was provided in Theorem 5 which will be useful when a closed-form likelihood function of all data can be obtained.

There are still cases where the existing tools developed in the present paper are not sufficient. We use the degenerate signal model in Example 4 to illustrate this point. Recall that for the case with $X_1 = X_2$ and 1-bit quantizer at each node, the optimal decentralized quantization is equivalent to a 2-bit quantization of the observation in a centralized inference system. Clearly, the optimum data reduction would be to find...
the minimum sufficient statistic [2] prior to quantization. As the minimum sufficient statistic is a function of any other sufficient statistic, it is apparent that any locally sufficient statistic pair \((T_1(X_1), T_2(X_2))\) retains the optimal inference performance.

The above argument can also be made more rigorous by expanding the Bayesian risk. Let \(T_1(X_1)\) be a sufficient statistic for \(\theta\) with respect to \(X_1\). When \(X_1 = X_2\),

\[
p(x_1, x_2, \theta) = p(x_1, \theta)\delta(x_1 - x_2) \\
\overset{(a)}{=} p(x_1)p(\theta|T_1(x_1))\delta(x_1 - x_2), \tag{20}
\]

where \(\delta(\cdot)\) is the Dirac delta function and \((a)\) is from Lemma \[1\]. Then we have

\[
R = \int_{\theta} \int_{x_1} \int_{x_2} d[\theta, h(\gamma_1(x_1), \gamma_2(x_2))]|p(x_1, x_2, \theta)|dx_1dx_2d\theta \\
= \int_{\theta} \int_{x_1} \int_{x_2} d[\theta, h(\gamma_1(x_1), \gamma_2(x_2))]|p(x_1)p(\theta|T_1(x_1))|dx_1dx_2d\theta \\
\cdot \delta(x_1 - x_2)d\theta \\
= \int_{\theta} \int_{x_1} d[\theta, h(\gamma_1(x_1), \gamma_2(x_1))]|p(x_1)p(\theta|T_1(x_1))|dx_1d\theta \\
\overset{(b)}{=} \int_{x_1} \alpha_1(u_1, x_1)|p(x_1)|dx_1,
\]

where

\[
u_1 \triangleq \gamma_1(x_1), \\
\alpha_1(u_1, x_1) \triangleq \int_{\theta} d[\theta, h(\gamma_1(x_1), \gamma_2(x_1))]|p(\theta|T_1(x_1))|d\theta.
\]

Given the optimal quantizer \(\gamma_2^*(\cdot)\) and estimator \(h^*(\cdot)\), we see that \(\alpha_1(u_1, x_1)\) depends on \(x_1\) only through \(T_1(x_1)\). The same argument shows that \(\gamma_2^*(\cdot)\) is a function of the sufficient statistic \(T_2(X_2)\) at the second node. Thus any local sufficient statistics \((T_1(X_1), T_2(X_2))\) can be used to achieve the same optimal inference performance. Note that while any local sufficient statistics \((T_1(X_1), T_2(X_2))\) preserve the optimal inference performance for this degraded observation model, they may not achieve the same degree of data reduction as that of the minimal sufficient statistic.

However, it is clear that Theorems 4 and 5 do not apply to this example, as the joint probability \[20\] can not be formulated in the form of \[19\]. Searching for more general conditions to ensure the structural optimality of data reduction in the presence of quantization constraint will be our future work.
