Electron-seeded ALP production and ALP decay in an oscillating electromagnetic field

B. King

Abstract

Certain models involving ALPs (axion-like-particles) allow for the coupling of scalars and pseudoscalars to fermions. A derivation of the total rate for production of massive scalars and pseudoscalars by an electron in a monochromatic, circularly-polarised electromagnetic background is presented. In addition, a derivation and the total rate for the decay of massive scalars and pseudoscalars into electron-positron pairs in the same electromagnetic background is given. We conclude by approximating the total yield of ALP production for a typical laser-particle experimental scenario.

1. Introduction

The spontaneous breaking of global symmetries in beyond-the-standard-model theories can give rise to scalar or pseudoscalar particles which are commonly referred to as ALPs (axion-like-particles). The original axion is a pseudoscalar that arises when the Peccei-Quinn [1] symmetry is broken at a very high energy scale to give rise to CP violation in QCD, thereby posing a potential solution to the so-called strong-CP problem. Whereas axions that solve the strong-CP problem are bound to the pseudoscalar result.

The QED counterpart of ALP production by an electron in an electromagnetic field is Compton scattering. First studied over sixty years ago [22, 23, 24, 25, 26], the prediction of an increased effective electron mass due to the charge-field coupling, was recently confirmed in experiment [27, 28, 29]. The QED counterpart of ALP decay to an electron-positron pair in an EM background is photon-seeded pair-creation [22, 30, 31] (photoproduction of a scalar pair in a circularly-polarised monochromatic background has also been considered [32]). The combination of ALP creation and subsequent decay is analogous to the trident process in QED. Although being measured twenty years ago in the landmark E144 experiment at SLAC [33], the trident process in a strong EM background presents numerous theoretical challenges and has recently been measured [34, 35, 36, 37, 38]. Using the large numbers of photons, such as intense laser pulses, for the generation of ALPs in an external EM (electromagnetic) field is Compton scattering.

The diphoton-ALP coupling in several ALP models suggests that one may also consider employing sources of large numbers of photons, such as intense laser pulses, for the generation of ALPs, and a regeneration region using inhomogeneous magnetic fields, as well as beam dump KEK [39]. Various experimental searches have been performed to detect ALPs and place increasingly stringent bounds on ALP models. Examples include helioscopes such as CAST [40] that use magnetic fields to regenerate axions emitted from the sun, LSW (light-shining-through-the-wall) experiments such as the ALPS experiment [41] that use an optical cavity to create ALPs and a regeneration region using inhomogeneous magnetic fields, as well as beam dump KEK [42].

The diphoton-ALP coupling in several ALP models suggests that one may also consider employing sources of large numbers of photons, such as intense laser pulses, for the generation of ALPs, and a regeneration region using inhomogeneous magnetic fields, as well as beam dump KEK [42].

The spontaneity breaking of global symmetries in beyond-the-standard-model theories can give rise to scalar or pseudoscalar particles which are commonly referred to as ALPs (axion-like-particles). The original axion is a pseudoscalar that arises when the Peccei-Quinn [1] symmetry is broken at a very high energy scale to give rise to CP violation in QCD, thereby posing a potential solution to the so-called strong-CP problem. Whereas axions that solve the strong-CP problem are bound to the pseudoscalar result.

The QED counterpart of ALP production by an electron in an electromagnetic field is Compton scattering. First studied over sixty years ago [22, 23, 24, 25, 26], the prediction of an increased effective electron mass due to the charge-field coupling, was recently confirmed in experiment [27, 28, 29]. The QED counterpart of ALP decay to an electron-positron pair in an EM background is photon-seeded pair-creation [22, 30, 31] (photoproduction of a scalar pair in a circularly-polarised monochromatic background has also been considered [32]). The combination of ALP creation and subsequent decay is analogous to the trident process in QED. Although being measured twenty years ago in the landmark E144 experiment at SLAC [33], the trident process in a strong EM background presents numerous theoretical challenges and has recently been measured [34, 35, 36, 37, 38]. Using massive scalars rather than virtual photons offers a simpler system to understand the main issues such as the relative importance of one-step and two-step processes. Reviews of strong-field QED can be found in [39, 40, 41, 42].

In the current letter, four processes are considered in a monochromatic electromagnetic background: i) massive scalar production by an electron; ii) the decay of a massive scalar to an electron-positron pair and iii) and iv) the same two processes for a pseudoscalar. We present only an outline of the derivation, highlighting steps important to the massive scalar case, as the derivation of equivalent QED processes already exist in the literature [43]. Following derivation of the scalar cases, we state the pseudoscalar result.

2. ALP production by an electron

The scattering matrix element for the massive scalar production depicted by the Feynman diagram in Fig. 1(a) is:

\[ S_{fi} = i g_{fi} \int d^4k \, \psi_{i} \gamma_{0} \phi_{f} \psi_{j}. \]  (1)
\( \kappa \) is a classical nonlinearity parameter quantifying the strength of polarisation and monochromatic:

\[
\kappa \cdot \text{polarised and monochromatic}.
\]

The coupling of the fermions to the EM background to all orders is incorporated using the Furry picture, in which the S-matrix is expanded as a perturbation around solutions to the Dirac equation in a given EM background (so-called "dressed states"). The Volkov wavefunction:

\[
\psi_p = \left[ 1 + \frac{\not{\kappa}}{2 \kappa \cdot p} \right] \frac{u_p}{\sqrt{2 \kappa \cdot p \sqrt{\hbar V}}} e^{-i p \cdot x - i \alpha_s/2}, \\
U_p(\varphi) = \int e^{i \varphi \cdot \kappa} \frac{p \cdot a(\varphi)}{\kappa \cdot p} \frac{\alpha_s'(\varphi)}{2 \kappa \cdot p} \, d\varphi.
\]

(2)

describes an electron of charge \( e \), momentum \( p \) satisfying the on-shell condition \( p^2 = m_e^2 \), with free-electron spinor \( u_p \), propagating in a plane wave background with scaled gauge potential \( a(\varphi) = eA(\varphi) \) and phase \( \varphi = \kappa \cdot x \), with wavevector \( \kappa \) such that \( \kappa \cdot \alpha = \kappa \cdot \kappa = 0 \). We choose the background to be circularly-polarised and monochromatic:

\[
a(\varphi) = m\xi (\varepsilon \cos \varphi + \tilde{\varepsilon} \sin \varphi),
\]

for \( \varepsilon \cdot \varepsilon = \tilde{\varepsilon} \cdot \tilde{\varepsilon} = -1 \) and \( \varepsilon \cdot \tilde{\varepsilon} = 0 \), and \( \xi \) is the classical nonlinearity parameter quantifying the strength of the EM background field. We choose the lab frame in which \( \kappa = \varepsilon \delta(1, 0, 0, 1), \varepsilon = (0, 1, 0, 0) \) and \( \tilde{\varepsilon} = (0, 0, 1, 0) \). The massive scalar is described by the plane-wave state:

\[
\phi = \frac{1}{\sqrt{2 \kappa \cdot p \sqrt{\hbar V}}} e^{i \varphi k \cdot \kappa},
\]

(4)

with momentum \( k \) satisfying the on-shell condition \( k^2 = m^2 \). The form of the scattering matrix element is then:

\[
S_{\beta} = \frac{i g_{\text{se}}}{\sqrt{2 \kappa \cdot p \sqrt{\hbar V}}} \int d^4 \chi \left[ e^{i \chi \cdot(p - q - \beta \kappa - \alpha_s \gamma s + \alpha_s \gamma s \cdot \kappa)} \right] \alpha_s \left[ 1 + \frac{\not{k}}{2 \kappa \cdot q} \right] \alpha_s \left[ 1 + \frac{\not{\kappa}}{2 \kappa \cdot p} \right] u_p,
\]

(5)

where

\[
\alpha_s = m\xi \left( \frac{p \cdot \varepsilon}{\kappa \cdot p} - \frac{q \cdot \tilde{\varepsilon}}{\kappa \cdot q} \right), \quad \alpha_c = m\xi \left( \frac{p \cdot \tilde{\varepsilon}}{\kappa \cdot p} - \frac{q \cdot \varepsilon}{\kappa \cdot q} \right), \quad \beta = -\frac{(m\xi)^2}{2} \left( \frac{1}{\kappa \cdot p} - \frac{1}{\kappa \cdot q} \right).
\]

It is advisable to deal with the integral after mod-squaring and taking the trace to simplify evaluation of the \( x^-=\varphi/\kappa_0 \) integral (\( x^0 = \kappa_0 - x^3 \) is the lightfront co-ordinate comoving with the background field). One then arrives at

\[
\frac{1}{2} \sum_{\text{spin}} |S_{\beta}|^2 = \frac{g_{\text{se}}^2}{V^2} \int \frac{d^4 x}{2^3 \kappa \cdot q \sqrt{\hbar V}} e^{-i (x' \cdot (p - q - k - \beta \kappa - \alpha_s \gamma s + \alpha_s \gamma s \cdot \kappa))} \times \sum_{s, s'} e^{-i (s' - s) / \kappa} T_{s, s'}
\]

(6)

if the Jacobi-Anger expansion \([45]\) is used:

\[
e^{-i z \sin(\varphi - \varphi_0)} = \sum_{s = 0}^{\infty} J_s(z) e^{-i s \varphi - \varphi_0},
\]

(7)

where \( J_s(z) \) is the Bessel function of the first kind and in the current calculation, we have:

\[
z^2 = \alpha^2 + \tilde{\alpha}^2; \quad \cos \varphi_0 = \frac{\alpha_\kappa}{z}; \quad \sin \varphi_0 = \frac{\alpha_\varepsilon}{z}
\]

and \( T_{s, s'} \) is the result of the trace, which we give later in a more simplified form. Performing the spatial integrals in \( x \) and \( x' \), one has to deal with the combination:

\[
\delta^{(4)}(p - q - k - (\beta - s) \kappa) \delta^{(4)}(p - q - k - (\beta - s') \kappa).
\]

This can be simplified into:

\[
\delta^{(4)}(p - q - k - (\beta - s) \kappa) \frac{V}{(2\pi)^3} \frac{p^b}{\kappa \cdot p} \delta(s - s'),
\]

by considering the combination

\[
\delta^{(4)}((s - s') \kappa) \frac{\delta(s - s')}{\delta(s - s')} = \frac{V}{(2\pi)^3} \frac{dt}{d\varphi} = \frac{V}{(2\pi)^3} \frac{dt}{d\varphi} \frac{d\varphi}{d\tau},
\]

(8)

where \( \tau \) is the proper time, and using the result that for an electron in a plane wave EM background, \( \kappa \cdot \kappa = m d\varphi/d\tau \) is a constant \([44]\). Defining the probability for massive scalar production by an electron as \( P_{e^{-\phi}} \), through:

\[
P_{e^{-\phi}} = V^2 \int \frac{d^4 k}{(2\pi)^3} \frac{d^4 q}{(2\pi)^3} \sum_{\text{spin}} |S_{\beta}|^2,
\]

(8)

one has the intermediate step:

\[
P_{e^{-\phi}} = \frac{g_{\text{se}}^2}{4\pi \kappa \cdot p} \int \frac{d^4 k}{2k^0} \frac{d^4 q}{2q^0} \sum_{s, s'} \delta(s - s') \times \delta^{(4)}(p - q - k - (\beta - s) \kappa) T_{s, s'}.
\]

(9)

Here we notice the clear appearance of global momentum conservation:

\[
\mathbf{p} + s \kappa = \mathbf{q} + k,
\]

where we define the electron quasimomentum, \( \mathbf{p} = p - (\alpha_s \gamma s \cdot \kappa) \kappa \), and the relation to the effective mass \( m_s \) via \( \mathbf{p}^2 = m_s^2 \), giving \( m_s^2 = m^2(1 + \xi^2) \) for a circularly-polarised background \([46, 47]\). Moreover the integer \( s \) is suggestive as the number of photons of frequency \( \kappa_0 \) absorbed from the EM background. Let us now deal with the final delta-function by recognising:

\[
\sum_{s, s'} \delta(s - s') = \int \frac{d\varphi}{2\pi} \sum_s.
\]
and since the phase integral is divergent, let us define the rate per phase $R^{-\Delta\phi} = R^{-\Delta\phi}/\int \! d\phi$. In addition, let us write this rate as a sum over the rate for each harmonic $s$:

$$R_{s}^{-\Delta\phi} = \sum_{s=0}^{\infty} R_{s}^{-\Delta\phi},$$

where $s_0^\phi$ is some threshold integer number of photons (which we will later define in terms of the integration variable), above which a scalar with mass $\sqrt{m^2}$ can be produced by the electron. If the $q$ integral is performed in Eq. (9), we have:

$$R_{s}^{-\Delta\phi} = \frac{g_{\phi\epsilon}^2}{16\pi} \int d^4k \left( \frac{\theta^{(k)}(\theta^{(q)})}{8\pi^2 \kappa \cdot \rho} \delta(k^2 - m^2) \delta(q^2 - m^2) T_{s,s} \right).$$

(10)

Suppose the $k$ integral is written as $d^3k = dk^+dk^-dk^2d\psi/4$, where $k^+ = k^0 \pm k^3$ are lightfront co-ordinates and $\psi$ is the polar angle in the $k^+ = (k^1, k^2)$ plane. Then by using the remaining delta-functions to integrate in $|k|^2$ and $k^+$, it can be shown the integrand is independent of the angle $\psi$. We then have:

$$R_{s}^{-\Delta\phi} = \frac{g_{\phi\epsilon}^2}{16\pi} \int \frac{d(\kappa \cdot k)}{(\kappa \cdot \rho)^2} \theta(\kappa \cdot k) \theta(\kappa \cdot \rho - \kappa \cdot k) \left| T_{s,s} \right|^2.$$

(11)

In order to make a comparison with literature results on the QED process of NLC, we rewrite this integration as:

$$R_{s}^{-\Delta\phi} = \frac{g_{\phi\epsilon}^2}{16\pi \eta_p} \int_{u_\phi}^{u_{t}} \frac{du}{1 + u} \left[ \left( 4 - \delta^2 \right) I_2(z_\phi^s) + \frac{u^2}{2(1 + u)} \left( I_{s+1}(z_\phi^s) + I_{s-1}(z_\phi^s) - 2I_2(z_\phi^s) \right) \right].$$

(12)

where we define the energy parameter $\eta_p = \kappa \cdot p/m^2$, and the ALP mass parameter $\delta = m_\phi/m$, and where:

$$\left( z_\phi^s \right)^2 = \left( \frac{2 \kappa^2}{1 + \xi^2} \right)^2 \frac{u}{u_t} \left( 1 - \frac{u}{u_t} \right) - \delta^2 = (1 + u) \eta_p.$$

(13)

and $u = \eta_p/\eta_q$ with $\eta_q = \eta_p - \eta_k$ and $u_\phi = 2s\eta_\phi^s$ with $\eta_\phi^s = \kappa \cdot \rho/m^2$. Since $z^* > 0$ and $z \in \mathbb{R}$, a condition is placed upon the range of integration of the variable $u > 0$, namely that the integration bounds $u_\phi$ are given by:

$$u_\phi = 2s\eta_\phi^s - \delta^2 = \frac{2s\eta_\phi^s - \delta^2}{(1 + \xi^2)^2} \left[ 1 + \sqrt{1 - \frac{4(1 + \xi^2)\delta^2}{(2s\eta_\phi^s - \delta^2)^2}} \right].$$

(14)

where we choose the range of parameters in which $u_\phi^s \geq u_\phi^s \geq 0$. We note that in the zero-mass limit, $\delta \to 0$, $u_\phi \to u_t$, and $u_\phi \to 0$ and $z_\phi^2$ tends to the standard argument for NLC of a massless photon in a circularly-polarised monochromatic background [43]. In the zero-mass limit, the form of the integrand is slightly different to the standard NLC case. First, the coefficient of the first $I_j$ term has a different sign and the factor 2 coefficient before the bracket of three squared Bessel functions is missing. Both of these originate from the different trace of the electron-scalar interaction compared with the electron-photon interaction in QED. Second, the coefficient of the entire integral is a factor $1/4$ smaller than the analogous QED result [48]. This is the well-known factor that originates from the missing polarisation sum in a scalar analogue of a photon interaction. (Recent calculations of NLC in a monochromatic background in scalar QED demonstrate the same 1/4 pre-factor [49,50].)

Just as in NLC, there exists an interval in $u$ for each harmonic, the so-called “harmonic range”. The difference here is that when the scalar mass is increased, this harmonic range is reduced on both sides, as displayed in Fig. 2(a). The heaviest scalar that can be produced at a given harmonic has a mass parameter:

$$\delta = 2 \left( 1 + \eta_p + \xi^2 - \sqrt{(1 + \xi^2)(1 + 2\eta_p + \xi^2)} \right).$$

(15)

indicated by the horizontal dashed lines in Fig. 2(a) (this can be derived by finding the value of $\delta$ such that $u_\phi^s = u_\phi^s$). Furthermore, in Fig. 2(a) it is shown how this suppression of the range affects larger values of $\xi$ more than smaller ones (this trend is continued for higher harmonics).

Another effect of a non-zero scalar mass is the appearance of a threshold number of photons that must be taken from the background field before the scalar can be scattered. By squaring the centre-of-mass energy, we find that:

$$2s\eta_p = \delta^2 \eta_p + m^2 \eta_\phi + \delta \eta_p \frac{(q^+ \eta_k - k^+ \eta_\phi)}{\kappa \cdot \rho \cdot \kappa \cdot k}.$$}

(16)

Therefore the threshold number of photons required to create a scalar with mass $\delta$ is $s_0^\phi$ where

$$s_0^\phi = \left[ \frac{\delta}{\eta_p} \left( \delta + \sqrt{1 + \xi^2} \right) \right].$$

(17)

([•] denotes the ceiling function), which reduces to $s_0^\phi = 0$ in the massless scalar limit, analogous to NLC of massless photons in QED. The effect on the harmonic rate of having a threshold number of photons for the scattering of a massive scalar is evident in Fig. 2(b). It is also apparent that even for many harmonics above the threshold, the scalar production rate is still suppressed compared to the zero-mass case. Also from Fig. 2(b), it is clear that the higher the scalar mass, the larger the suppression for the above-threshold harmonics.

The scattering matrix element for massive pseudoscalar production can be written [21]:

$$S_{ji} = i \sum_{s} \int d^3x \, \varphi^* \psi^* \gamma_5 \psi,$$

where we denote a pseudoscalar by $\varphi$. The derivation of the total rate follows identical lines. If we define the total pseudo-
Figure 2: The effect of the scalar mass on scalar production by an electron for \( \eta_p = 0.0025 \) (\( g_{de} = 1 \)).

The coupled rate \( R_i^{\phi\psi} = \sum_{s>0} R_i^{s\phi\psi} \), then we find:

\[
R_i^{s\phi\psi} = \frac{g_{de}^2}{16\pi\eta_p} \int_{u_i}^{u_f} du \frac{u^2}{(1 + u)^2} \left[ -\delta^2 \right. \\
+ \left. \frac{\delta^2}{2(1 + u)} \left( J_{s+1}^2(z_s^0) + J_{s-1}^2(z_s^0) - 2J_s^2(z_s^0) \right) \right],
\]

where the difference to the massive scalar case Eq. (12) is entirely due to the different sign of the mass term in the trace. As the kinematics are the same, so is the Bessel argument \( z_s^0 \), already given through Eq. (13).

2.1. Weak-field limit of ALP production by an electron

If \( \xi \ll 1 \), the background plane wave is termed “weak” and the coupling to electron and positron states is perturbative. For the analogous QED process of NLC, the fundamental harmonic \( (s = 1) \) of the weak-field limit of a monochromatic background is identical to the Klein-Nishina formula [23]. Since \( z_s^0 \ll \xi \), we can arrive at the weak-field limit using the replacements:

\[
J_{s+1}^2(z_s^0) + J_{s-1}^2(z_s^0) - 2J_s^2(z_s^0) \approx 1 + O(\xi^2);
J_s^2(z_s^0) \approx \frac{(z_s^0)^2}{4} + O(z^4).
\]

This then leads to:

\[
R_i^{s\phi\psi} \approx \frac{g_{de}^2}{8\pi\eta_p} \int_{u_i}^{u_f} du \frac{u^2}{(1 + u)^2} \left[ \frac{1}{2} \frac{u^2}{1 + u} \right. \\
+ \left. 4 - \delta^2 \right] \left( 1 - \frac{u}{u_1} \right) - \frac{\delta^2}{4\eta_p} \left. \right]
\]

An expansion of the result to leading order in \( \delta^2 \) gives:

\[
R_i^{s\phi\psi} \approx \frac{g_{de}^2}{8\pi\eta_p} \left\{ \frac{1}{(1 + u_1)^2} \left[ \frac{3}{4} \frac{u_1^2}{2} + 16 + \frac{8}{u_1} \right] \\
+ \left[ \frac{1}{2} + \frac{4}{u_1} + \frac{8}{u_1^2} \right] \ln(1 + u_1) \\
+ \delta^2 \left[ \frac{2}{u_1} + \frac{1}{\eta_p} + \frac{1}{u_1} + \frac{2}{u_1^2} \right] \ln(1 + u_1) \right\}.
\]

The pseudoscalar result is then:

\[
R_i^{s\phi\psi} \approx \frac{g_{de}^2}{8\pi\eta_p} \left\{ \frac{1}{(1 + u_1)^2} \left[ \frac{3}{4} \frac{u_1^2}{2} + \frac{1}{2} \right] - \frac{1}{2} \ln(1 + u_1) \\
+ \delta^2 \left[ \frac{2}{u_1} + \frac{1}{\eta_p} + \frac{2}{u_1^2} \right] \ln(1 + u_1) \right\}.
\]

In a recent calculation of linear Compton production of a massive scalar and pseudoscalar in an external plane-wave field [51], the long-pulse limit was found to agree with Eqs. (22) and (23) when the background was circularly-polarised.

3. ALP decay to electron-positron pair

The scattering matrix element for the decay of a massive scalar to an electron-positron pair depicted by the Feynman diagram in Fig. (1b) is:

\[
S_{ji} = ig_{de} \int d^4x \bar{\psi}_j \gamma_\mu \psi_i \gamma^\mu \psi^+_q,
\]

where the outgoing positron Volkov wavefunction is

\[
\psi^+_q = \left[ 1 - \frac{\not{q}}{2\xi_{+}} \right] \frac{v_q}{\sqrt{2}q^0} e^{iq\cdot x - iU_\omega(x)}.
\]

for free-positron spinor \( v_q \). The derivation follows very much the structure of the previous section. Let us define the total rate for a single massive scalar to decay to an electron-positron-pair as:

\[
R_i^{\phi\to\psi\psi} = \sum_{s=0}^{\infty} R_i^{s\phi\psi}.
\]

Just as for Eq. (16), but for the pair-creation kinematics, squaring the centre-of-mass energy leads to a threshold number of photons:

\[
s^2_q = \left[ \frac{1}{2\eta_k} \left( \frac{4m_e^2}{m^2} - \delta^2 \right) \right].
\]

In other words, the heavier the scalar, the lower the threshold for pair-creation. We then find:

\[
R_i^{\phi\to\psi\psi} \approx \frac{g_{de}^2}{16\pi\eta_k} \int_{\sqrt{\frac{v}{\sqrt{\gamma}v(y-1)}}} d\sqrt{\gamma} \left[ -4 + \delta^2 \right] J_0^2(z_s^0) \\
+ 2v^2 \left[ J_{s+1}^2(z_s^0) + J_{s-1}^2(z_s^0) - 2J_s^2(z_s^0) \right].
\]
(28)

where:

\[ v^s \approx v^0 + \frac{\delta^2}{4(1 + \xi^2)} \]

\[ v^0 = \frac{s \eta_k m^2}{2m_\gamma}. \]

(We note that the relation between \( v \) and the lightfront momentum \( p^\perp \) (which occurs naturally when integrating over outgoing particle momenta of the mod-squared scattering matrix element), is nonlinear and splits the original integral into two identical branches.) How the kinematic range and probability change for pair-creation when the scalar mass parameter \( \delta \) is increased from 0 to 2 in equal increments, is shown in Fig. 3(a). The lowest curve is for \( \delta = 0 \) and corresponds to a threshold \( \xi^0 \) for \( \xi = 0.1 \). \( \eta_k = 1 \) and \( \delta \) evenly spaced between 0 and 2 (\( g_{\gamma e} = 1 \)).

Figure 3: The dependency of pair-creation on scalar mass.

For the case of pseudoscalar decay to an electron-positron pair in a monochromatic background, the scattering matrix element is given by:

\[ S_{\beta} = i g_{\gamma e} \int d^4 x \phi_k \bar{\psi}_e \gamma_5 \psi_\gamma. \]

(29)

As for ALP production, in the case of ALP decay, it is only the mass term that changes sign between the scalar and pseudoscalar cases. Therefore, we skip straight to the result for the total pseudoscalar rate \( R_\perp^{\phi\rightarrow e^+ e^-} = \sum_{\eta_k} R_\perp^{\phi e}e^\pm \) where:

\[ R_\perp^{\phi e} = \frac{g_{\gamma e}^2}{16\pi \eta_k} \int_1^{\infty} \frac{dv}{v} \frac{d^3 \vec{k}}{(2\pi)^3} |\langle \delta^2 f^2(z_{\pm}) + 2v^2 e^2 (J_{\delta+1}(z_{\pm}) + J_{\delta-1}(z_{\pm}) − 2J_{\delta}(z_{\pm}) \rangle| \]

(30)

For light pseudoscalars with \( \delta \ll 1 \), we see from Eq. (30) a large suppression in the rate. Therefore light pseudoscalars are much more stable than light scalars when propagating through weak EM backgrounds.

3.1. Weak-field limit of ALP decay to electron-positron pair

Using the same expansion as Eq. (29) when \( \xi \ll 1 \), we find the weak-field limit of the ALP decay in a monochromatic background to be given by:

\[ R_\perp^{\phi \rightarrow e^+ e^-} \approx \frac{g_{\gamma e}^2 \xi^2}{8\pi \eta_k^2 \sqrt{(t + 1)}} \left[ \left( \frac{2t}{\xi^2} + 2t + 1 \right) \sinh^{-1} \sqrt{t} \right] \]

(31)

where we have defined the shorthand: \( \delta^2 = \delta^2 - 4 \) and the Mandelstam-like variable \( t = 1 - (\kappa + s \xi^2) / 4m^2 \), equal to the relative difference of the centre-of-mass energy squared to the pair rest energy squared.

4. Discussion

Although the diagram for ALP production by an electron in an EM plane wave is very similar to nonlinear Compton scattering, when a massive scalar is emitted, the kinematics are more akin to pair-creation in an EM plane wave. In particular, there appears a threshold number of external-field photons that depends on the scalar’s mass, the frequency of the background and the energy of the electron.

Pair creation in a plane wave EM background by a massive scalar differs from pair-creation from a photon, in that the mass of the scalar lowers the threshold number of photons required for the process to proceed. As the scalar mass is increased, the process changes from being a stimulated to a spontaneous process.

We do not perform here an analysis of the ALP production and regeneration rates expected in experiment, however we give some orders of magnitude for the production mechanism. The dependency of the total rate for massless scalar decay by an electron is shown in Fig. 4 for \( g_{\gamma e} = 1 \) and \( \eta_p = 6 \cdot 10^{-6} \)
(equivalent to an electron at rest in a monochromatic background of frequency $\nu_0 = 1.55$ eV -- the frequency of a 800 nm laser beam). It can be seen in Fig. 4(a) that as $N_p \to \infty$, the pseudoscalar and scalar rates tend to the same values. A similar behaviour was found in the monochromatic limit of a direct calculation of these processes in a background pulse [51].

![Figure 4](https://example.com/f4.png)

(a) A log-log plot of how the pseudoscalar rate (dashed lines) and scalar rates (solid lines) depend on $N_p$, for $\xi = 2$ (upper pair of coalescing lines) and $\xi = 0.1$ (lower pair of coalescing lines).

(b) The dependency of pair production on scalar mass and the fit $R^{\Phi,\sigma} \approx 0.025 \xi^2$ (dashed) for $\xi = 1$, and $\Phi = 6 \times 10^{-4}$, $m_s = 1$ meV (making $\delta = 2 \times 10^{-9}$).

Figure 4: Dependency of total scalar rate on $\xi$ and $N_p$.

To estimate the total number of scalars produced, we introduce for $N_p = 6 \times 10^{-6}$, the weak-field fit: $R^{\Phi,\sigma} \approx 0.025 \xi^2$, the accuracy of which is plotted in Fig. 4(b). (This scaling with $\xi$ is clear from the weak-field result in Eq. (22).) Although we have picked a specific value of $N_p$, we see from Fig. 4(a), that for all $N_p \lesssim 10^{-2}$, the rate of scalar production is not very sensitive to the value of $N_p$. Therefore, for $\xi \ll 1$, we can estimate the yield per collision as $N_s \approx 0.025N\xi^2 \Phi$ or:

$$N_s \approx 4 \times 10^8 \Phi \left(\frac{N_s}{10^6}\right) \left(\frac{I}{10^{19}\text{Wcm}^{-2}}\right) \left(\frac{1.55\text{ eV}}{\nu_0}\right) \left(\frac{\tau}{100\text{ fs}}\right)$$

where $\Phi = \nu_0 \tau$ is the laser pulse phase length and $\tau$ is the pulse duration, and where $N_s$ is the number of electron seeds. If one takes a lab-based limit on $\gamma_{ee}$ from underground detectors of the order $\sim O(10^{-11})$ [14] (astrophysical bounds are of the order of $\sim O(10^{-13})$ for axions in the meV range [52]), and an optical long pulse duration of $\Phi \sim O(10^5)$ or X-ray long pulse duration of $\Phi \sim O(10^6)$, then to achieve $N_s \gg 1$, it is beneficial to use a large number of electron seeds. Laser-wakefield accelerated electron beams containing of the order of $10^9$ to $10^{10}$ electrons have been demonstrated in the lab [53, 54]. Moreover, as we see from Fig. 3 the initial momentum of the electrons is not crucial. The limiting factor is more the volume of the laser pulse for which $\xi$ is sufficiently high, as well as the laser's repetition rate. The BELLA laser facility supplies 1 PW at a repetition rate of 1 Hz and has demonstrated a peak laser intensity of over $10^{19}$ W cm$^{-2}$ [55]. With the development of modern high-intensity laser systems, these values are set to become even more favourable.

Therefore, the experimental set-up of colliding a high rep-rate intense laser pulse with an electron gas may not imme-

ately provide as stringent limits as astrophysical bounds, however, by varying the electron-beam parameters, a large range of scalar masses can be probed. Moreover, such an experiment would be unique, in that it would provide the first fully lab-based, model-independent probe of $\gamma_{ee}$.
