Low-Frequency Raman Spectroscopy of Few-Layer 2H-SnS₂

Tharith Sriv¹, Kangwon Kim¹ & Hyeonsik Cheong¹

We investigated interlayer phonon modes of mechanically exfoliated few-layer 2H-SnS₂ samples by using room temperature low-frequency micro-Raman spectroscopy. Raman measurements were performed using laser wavelengths of 441.6, 514.4, 532 and 632.8 nm with power below 100 μW and inside a vacuum chamber to avoid photo-oxidation. The intralayer \( \text{E}_g \) and \( \text{A}_{1g} \) modes are observed at ~206 cm\(^{-1}\) and 314 cm\(^{-1}\), respectively, but the \( \text{E}_g \) mode is much weaker for all excitation energies. The \( \text{A}_{1g} \) mode exhibits strong resonant enhancement for the 532 nm (2.33 eV) laser. In the low-frequency region, interlayer vibrational modes of shear and breathing modes are observed. These modes show characteristic dependence on the number of layers. The strengths of the interlayer interactions are estimated by fitting the interlayer mode frequencies using the linear chain model and are found to be \( 1.64 \times 10^{19} \text{ N} \cdot \text{m}^{-3} \) and \( 5.03 \times 10^{19} \text{ N} \cdot \text{m}^{-3} \) for the shear and breathing modes, respectively.

Interest in two-dimensional (2D) materials such as hexagonal boron nitride (hBN), black phosphorus (BP) and transition-metal dichalcogenides (TMDs) since the discovery¹ of graphene in 2004 has significantly increased due to their unique structures and properties. Most TMD materials such as MoS(e)₂ and WS(e)₂, are indirect band gap semiconductors with band gap energies in the visible range but become direct in the monolayer limit²–⁶. Recently, tin disulfide (SnS₂) has attracted much interest because it is recognized as earth-abundant, relatively cheap and low-toxic material. Additionally, it has been shown to have high on/off current ratios for field effect transistors⁷,⁸, fast photodetection⁹ suitable for flexible photodetectors from UV to IR¹⁰, interesting gas sensing property¹¹, and high optical absorption and photovoltaic activities¹².

SnS₂ is among the most important sulfide compounds of tin¹³,¹⁴ and has more than 70 polytypes¹⁵–²² differing from one another by stacking sequences of the individual sandwiched layers. The most common one is 2H-SnS₂ whose basic layer consists of a sheet of close-packed tin atoms sandwiched between two sheets of sulfur atoms²³–³². It should be noted that in the literature, SnS₂ with a structure identical to that of 1T-MoS₂ as shown in Fig. 1(a) is called 2H-SnS₂¹⁷–³², which should not be confused with the structure of 2H-MoS₂. In 2H-SnS₂, a metal atom is octahedrally coordinated by sulfur atoms, whereas the metal atom in 2H-MoS₂ possesses trigonal prismatic coordination¹⁶. Monolayers of 2H-SnS₂ are stacked exactly on top of one another to form 2H-polytype of bulk SnS₂. Between the neighboring layers of 2H-SnS₂, there exists weak van-der-Waals interaction¹⁰ offering easy mechanical cleavage along the c-axis down to monolayer. Bulk 2H-SnS₂ belongs to the symmetry group of \( D_{3d}^1 (P3m1) \) and has a trigonal structure with the lattice constants of \( a = 3.6486 \text{ Å} \) and \( c = 5.8992 \text{ Å} \). Unlike most TMDs, 2H-SnS₂ is projected to remain an indirect band gap semiconductor for all thicknesses, with the band gap ranging between 2.18 eV (bulk) and 2.41 eV (monolayer). Although chemical vapor deposition¹⁴ and molecular beam epitaxy²⁶ growths have been tried, large-area growth of few-layer SnS₂ has not been realized yet. At the moment, mechanical exfoliation from bulk crystals yields the highest quality few-layer samples.

Raman spectroscopy is one of the most widely used characterization tools for 2D layered materials to determine the number of layers as well as polytypes or strain effects. More importantly, one can use low-frequency Raman spectroscopy to study the interlayer interactions of few-layer materials by measuring the in-plane (shear) and out-of-plane (breathing) modes in the low-frequency region (<50 cm\(^{-1}\)). In the literature, the measured data of the shear and breathing modes are used to estimate the interlayer spring constants of the studied materials such as MoS₂ and WSe₂, MoSe₂, MoTe₂, WS₂, ReS(e)₂, Bi₂Te₃, and Bi₂Se₃, black phosphorus, and graphite by fitting the experimental data to the linear chain model (LCM). Additionally, Luo et al. reported that the
Results and Discussion

Figure 1(b,c) show the optical and AFM images of a 2H-SnS2 sample, respectively. The dotted outline in Fig. 1(b) indicates where monolayer (1L) is located. The AFM measurements of this sample indicate the presence of several thicknesses as indicated. The 1L 2H-SnS2 has a thickness of ~0.6 nm. Our AFM results show a step size of ~0.8 nm for 1L and ~1.4 nm for 2L, which is reasonable as there usually is a small extra thickness for the first layer in AFM measurements of 2D materials. This is either due to trapping of absorbed H2O molecules between the 2H-SnS2 and the SiO2/Si substrate or imperfect adhesion of the sample on the substrate. We measured multiple sets of samples with thicknesses ranging from 1L to 14L and bulk. It is worth mentioning that no sign of degradation was observed after our few-layer 2H-SnS2 samples had been left in ambient condition for several weeks, but AFM measurements performed few hours after being exposed to the laser beam in the Raman measurements in ambient air showed degradation caused by photo-oxidation (see Supplementary Information). We therefore carried out all Raman measurements with the sample kept inside a vacuum chamber.

Figure 2(a) shows the low- and high-frequency Raman spectra of 5L 2H-SnS2 measured with four excitation energies. Vertical dashed-lines are guides for the eye. It is seen that the Raman signals are strongest for the 2.33 eV (532 nm) excitation laser. The out-of-plane A1g mode at ~314 cm$^{-1}$ is most prominent. The E1u mode at ~206 cm$^{-1}$ is extremely weak and is barely resolved only in the spectrum taken with the excitation energy of 2.81 eV (441.6 nm). In the low-frequency region, the interlayer vibrational modes of in-plane shear (S) and out-of-plane breathing (B) modes are identified. Figure 2(b) shows the excitation energy dependence of the A1g mode for 1L to 14L 2H-SnS2. The 532 nm (2.33 eV) excitation laser provides the strongest intensity of the A1g mode, which implies that the band gap of few-layer 2H-SnS2 may be smaller than the recent theoretical prediction of 2.41 eV for 1L. Figure 2(c) shows the dependence of the Raman spectrum on the number of layers. In addition to the A1g and E1u modes, two other weak signals from A1u and A1g-LA (M) modes are observed for bulk or thick samples at ~353 cm$^{-1}$ and ~140 cm$^{-1}$, respectively. The A1u mode is an infrared mode but appear probably due to activation by lattice disorders, whereas the two-phonon scattering signal of A1g-LA (M) is weak due to the small scattering cross section. Figure 2(d) shows the E2g mode measured with the 441.6 nm excitation laser in cross polarization configuration since this excitation laser provided relatively stronger signals for the E2g mode. No clear shift is observed as the thickness increases. Figure 2(e) indicates the evolution of the Raman intensity and the peak position of the A1g mode as a function of the number of layers. The error bars indicate the spectral resolution of the setup. The intensity of the A1g mode evolves monotonically with the number of layers up to ~1L. This mode also shows a slight blue-shift from 1L to 3L, which is in good agreement with recent theoretical results

For 1L 2H-SnS2, there exist nine vibrational modes at the center of the Brillouin zone at the Γ point: \( \Gamma = A_{1g} + E_{1u} + 2A_{1u} + 2E_{2g} \). Among six optical phonon modes, there are three Raman active modes (A1g and E1u) and three infrared-active modes (A1u and E1u). The three acoustic modes belong to A1g and E1u. The Raman scattering intensity is proportional to \( |e \cdot \vec{R} \cdot e|^2 \) where \( e \) represents the polarization vector of the incident light, \( \vec{R} \) that of the scattered light, and \( \vec{R} \) the Raman tensor. The Raman tensors can be expressed as

Figure 1. (a) Crystal structure of monolayer 2H-SnS2. (b) Optical and (c) atomic force microscope (AFM) images of a mechanically exfoliated few-layer 2H-SnS2 sample on a SiO2/Si substrate.
In the backscattering geometry with the laser propagating in the $z$ direction, only the $E_g$ mode is observable in cross polarization, whereas both the $A_{1g}$ and $E_g$ modes can be observed in parallel polarization configuration. For the low-frequency interlayer modes that exist in 2L or thicker 2H-SnS$_2$, the shear modes correspond to $E_g$ and the breathing modes $A_{1g}$. By using polarized Raman measurements, one can thus distinguish shear and breathing modes unequivocally.

Figure 3(a) illustrates the polarization dependence of the Raman spectrum of 5L 2H-SnS$_2$. As a function of the relative scattering polarization angle with respect to the incident polarization direction, the intensities of the intralayer $A_{1g}$ mode and the interlayer breathing modes are modulated, whereas the intralayer $E_g$ mode and the interlayer shear modes are independent of the scattering polarization, which is consistent with the Raman

$$A_{1g} = \begin{pmatrix} a & 0 & 0 \\ 0 & a & 0 \\ 0 & 0 & b \end{pmatrix} \quad \text{and} \quad E_g = \begin{pmatrix} c & 0 & 0 \\ 0 & -c & -d \\ 0 & d & 0 \end{pmatrix} \begin{pmatrix} 0 & -c & -d \\ -c & 0 & 0 \\ -d & 0 & 0 \end{pmatrix}$$ (1)
tensor analysis above. Figure 3(b) illustrates the vibrations of in-plane shear and out-of-plane breathing. The evolution of the low-frequency interlayer vibrational modes as a function of the number of layers is shown in Fig. 3(c–e). The shear and breathing modes can be distinguished by using polarized Raman measurements as explained before. Figure 3(c) shows the shear modes measured in cross polarization, in which the breathing modes are suppressed. Up to 2 shear modes (S1 and S2) are identified, and their positions depend sensitively on the number of layers. Figure 3(d) shows similar spectra measured in parallel polarization. Here, both the shear and breathing modes are observed. By comparing with Fig. 3(c), one can unambiguously identify the breathing modes (B1 and B2). Figure 3(e) summarizes the evolution of the interlayer vibrational modes as a function of the number of layers. Since the high-frequency intralayer modes show little dependence on the number of layers beyond 3L, low-frequency Raman analysis would be the most reliable method to determine the number of layers of few-layer 2H-SnS$_2$.

As the low-frequency interlayer modes reflect the strength of the interlayer interaction, one can estimate the interlayer spring constants in the in-plane and out-of-plane directions by analyzing the frequencies of the shear and breathing modes, respectively. In the linear chain model\cite{36,41,49}, assuming that only interactions between nearest-neighbor layers are important and by neglecting the substrate and surface effects, the angular frequency of the $\alpha$-th shear (breathing) mode in $N$-layer 2H-SnS$_2$ is given by,
For the A4. Yan, T., Ye, J., Qiao, X., Tan, P. & Zhang, X. Exciton valley dynamics in monolayer WSe2 probed by the two-color ultrafast Kerr resolved. The 2.33 eV (532 nm) excitation laser provides the strongest Raman signals of intralayer information on materials parameters for device designs using few-layer 2H-SnS2. The interlayer vibrational modes are weaker than in most other layered materials. These results provide valuable information on materials parameters for device designs using few-layer 2H-SnS2. The force constants per unit area of 2H-SnS2 thus obtained with those of other layered materials found in the literature. The interlayer interaction in 2H-SnS2 is significantly weaker than in most materials compared.

In summary, we investigated lattice dynamics of mechanically-exfoliated few-layer 2H-SnS2 by room temperature low-frequency micro-Raman spectroscopy using four different excitation energies. In monolayer, the in-plane LA(1g) mode is most prominent, whereas in thick samples and bulk, the weak in-plane E2g mode as well as two additional modes such as A1g – LA(M) (∼140 cm⁻¹) and A1u (∼353 cm⁻¹) are resolved. The 2.33 eV (532 nm) excitation laser provides the strongest Raman signals of intralayer A1g mode and interlayer shear and breathing modes, whereas the E2g mode appears stronger for the 2.81 eV (441.6 nm) excitation. For the A1u mode, the Raman shift is slightly sensitive to thickness for 1L-3L, but not for thicker material. The shear and breathing modes show strong dependence on the thickness, which provides a robust criterion for determination of the thickness using Raman spectroscopy. The interlayer interactions obtained by analyzing the interlayer vibrational modes are weaker than in most other layered materials. These results provide valuable information on materials parameters for device designs using few-layer 2H-SnS2.

### Methods

Few-layer 2H-SnS2 samples were prepared from a SnS2 single-crystal (HQ Graphene) onto SiO2/Si substrates with 280 nm-thick oxide layer by mechanical exfoliation. The thickness of the samples was determined by atomic force microscope (AFM) and further confirmed by Raman measurements. The AFM measurements were performed by using a commercial AFM system (NT-MDT NTEGRA Spectra). Room temperature micro-Raman spectroscopy was conducted in backscattering geometry using four different excitation energies: the 441.6 nm (2.81 eV) line of a He-Cd laser, the 514.4 nm (2.41 eV) line of a diode-pumped laser (Cobolt), the 532 nm (2.33 eV) line of a diode-pumped solid-state (DPSS) laser, and the 632.8 nm (1.96 eV) line of a He-Ne laser. The laser beam was focused onto the samples by a 40× microscope objective lens (0.6NA), and the scattered light was collected and collimated by the same objective lens. The laser of power below 100 μW was used. All measurements were performed with the sample in a vacuum chamber to prevent photo-oxidation. AFM images [Supplementary Information Fig. S1] taken after Raman measurements confirmed that there were no apparent damages. Volume holographic filters (Ondax and OptiGrate) were used to access the low-frequency range below 50 cm⁻¹. The Raman scattering signals were dispersed by a Jobin-Yvon iHR550 spectrometer with a 2400 grooves/mm grating (400 nm blaze) and detected by a liquid-nitrogen-cooled back-illuminated charged-couple-device (CCD) detector. The spectral resolution was below 1 cm⁻¹.
