(February 23, 2018)

A simple model of a degenerate two-dimensional Bose liquid interacting with a fluctuating gauge field is investigated as a possible candidate to describe the charge degree of freedom in the normal state of the cuprate superconductors. We show that the fluctuating gauge field efficiently destroys superfluidity even in the Bose degenerate regime. We discuss the nature of the resulting normal state in terms of the geometric properties of the imaginary-time paths of the bosons. We will also present numerical results on the transport properties and the density correlations in the system. We find a transport scattering rate of $\hbar/\tau_n \sim 2k_B T$, consistent with the experiments on the cuprates in the normal state. We also find that the density correlations of our model resemble the charge correlations of the $t$-$J$ model.

PACS numbers: 74.20.Mn, 67.40.Db

We study the low-temperature behavior of repulsive bosons in a spatially fluctuating gauge field in two dimensions. This is motivated by the gauge theories of the $t$-$J$ model for the cuprate superconductors, where low-energy charge excitations are described by bosonic degrees of freedom. The internal gauge field of this model suppresses superfluidity in the Bose liquid, even below the Bose degeneracy temperature when there is significant exchange among the bosons. We can study the imaginary-time trajectories of the bosons in the path-integral representation of this model. We see that the boson world-lines retrace themselves in the presence of strong gauge fluctuations, giving rise to interesting dynamics in this degenerate but metallic Bose liquid.

We have studied this metallic state using quantum Monte Carlo techniques. We find that this model does indeed capture some of the long-wavelength charge properties which are common to the cuprate superconductors. This includes a linear temperature dependence of the transport scattering rate $1/\tau_n$, as deduced from a Drude-like optical conductivity from our model. This is consistent with experimental data on the cuprate superconductors near optimal doping. We also find that the density excitations in our model are qualitatively similar to those in the full $t$-$J$ model, by comparing our results with diagonalization results in the literature. A brief account of this work has already appeared.

I. MOTIVATION

The normal metallic state of the superconducting cuprates displays many non-Fermi-liquid properties. For instance, the in-plane resistivity of La$_2-x$Sr$_x$CuO$_4$ has a power-law temperature dependence of the form $\rho \propto T^n$ where $n$ increases from 1 to 1.5 with increasing hole doping. In particular, near optimal doping, the resistivity is linear in temperature up to 1000K. This linear-$T$ dependence is found in many of the cuprate superconductors with similar values of $d\rho/dT$ ($1.2\mu\Omega cm/K \pm 20\%$).

This should be contrasted with the quadratic temperature dependence of Fermi-liquid theory. Similarly, the transport relaxation rate appears to be universal among optimally-doped compounds: $1/\tau_n \simeq 2k_B T$ (from a two-component-model analysis of the optical conductivity in YBCO, LSCO, Bi2212, Bi2201). Transport in a magnetic field is also anomalous. The Hall coefficient indicates the existence of hole-like carriers in the doping range where superconductivity occurs. The Hall coefficient $R_H$ increases with decreasing temperature, but it remains smaller than the classical value of $1/n_h e c$ for a hole density of $n_h$ for a wide range of temperatures down to the superconducting transition. These compounds also have a small positive magnetoresistance with a temperature dependence different from conventional theory using $\tau_\text{tr}$.

The transport properties of these compounds appear to have common features in spite of considerable differences in the transition temperature and spin fluctuation properties among these compounds. This indicates that a common mechanism is responsible for the scattering of charge carriers in these materials. One might hope that this scattering mechanism can be understood in terms of a low-energy theory with a minimum number of microscopic parameters. In this paper, we study a Bose liquid in a fluctuating gauge field as a possible candidate for such an effective theory.

The anomalous transport behavior, together with other unusual features such as temperature-dependent magnetic susceptibility and non-Korringa behavior of the nuclear magnetic relaxation time, leads to the conclusion that the metallic state of the cuprates cannot be described in a simple Fermi-liquid scenario. It has been postulated that “spin-charge separation” is responsible for these anomalies. For instance, such a scenario might reconcile the apparent low density and hole-like character of the charge carriers with the observation of a large, electron-like Fermi surface in photoemission. Numerical studies of the $t$-$J$ model, which is believed to be a low-energy model of the cuprates, also provide some support.
for spin-charge separation, such as different energy scales for the spin and charge excitations, and the suppression of $2k_F$-scattering in the charge spectrum.

A model of spin-charge separation is a gauge theory where neutral spin-half fermions (“spinons”) and charge carriers (“holons”) interact via an internal U(1) gauge field. Physically, the transverse part of the gauge field is related to “spin chirality” fluctuations. In this picture, the charge properties of the system should be dominated by the behavior of the holons. We will study the holon subsystem in this paper, treating the spinon subsystem simply as a medium through which the gauge field propagates. To be more precise, we study a model of bosons with on-site repulsion in the presence of a spatially fluctuating magnetic field with short-range correlations. The repulsive interaction is necessary for the stability of the system, which means that one cannot treat this problem perturbatively starting from an ideal Bose gas. Previous studies have implicitly studied the non-degenerate regime of low density or high temperature, whereas the regime relevant to the cuprates is the degenerate regime where the thermal deBroglie wavelength of the bosons is greater than the mean particle spacing. A concern from earlier studies of the gauge model is that degenerate bosons would have strong diamagnetic response to the internal gauge field and hence effectively Bose-condense at a relatively high temperature ($k_B T_{BE} \sim 4\pi n_B t \sim 1000 K$). This would in fact restore Fermi-liquid behavior to the system. We shall show here that gauge fluctuations suppress this diamagnetic response and the bosons remain normal without strong diamagnetism at all finite temperatures. Furthermore, our numerical results indicate that the resistivity of this Bose metallic phase has a linear temperature dependence which is consistent with experiments.

Besides the possible relevance to the transport in the cuprate superconductors, the model we consider is of intrinsic theoretical interest. The model is a Bose version of the problem of a quantum particle in a random magnetic flux, which has received considerable attention in recent years. It is also related to frustrated spin systems and vortex glasses. However, since we deal exclusively with annealed averaging in this paper (see later), we cannot draw any direct conclusions about these problems with quenched disorder.

The rest of the paper is organized as follows. In section II, we review the connection between the gauge theory of the $t$-$J$ model and our boson model. In section III, we discuss the path-integral formalism which provides a convenient framework to visualize physical processes in terms of the imaginary-time paths of the bosons. In section IV, we look at the effects of the gauge field on the world-line geometry of the bosons. We will see that the partition function of the system is dominated by self-retracing world-line configurations. We will also argue that superfluidity is destroyed by the fluctuating gauge field, giving rise to a degenerate Bose metal. In the subsequent sections, we present the results of a quantum Monte Carlo study of this metallic phase. We will discuss the transport properties and the density correlations in this boson model.

## II. A BOSON GAUGE MODEL

In this section, we provide the motivation for studying an effective boson model from the gauge theory of the $t$-$J$ model, which describes the motion of vacancies in a doped Mott insulator:

$$
\mathcal{H} = -t_0 \sum_{\langle ij \rangle \sigma} (c^\dagger_{i \sigma} c_{j \sigma} + \text{h.c.}) + J \sum_{\langle ij \rangle} \mathbf{S}_i \cdot \mathbf{S}_j
$$

with the constraint of no double occupancy. Experimentally, $J \simeq 1500 K$ and $t_0/J \simeq 3$.

The constraint of no double occupancy allows us to write the creation of a physical hole in terms of the creation of a charged hard-core boson (holon) and the annihilation of a spin-half fermion (-spinon): $c_{i \sigma} = f_{i \sigma} b_i$. In terms of these slave bosons and fermions, the Hamiltonian of the $t$-$J$ model can be written as:

$$
\mathcal{H} = -t_0 \sum_{\langle ij \rangle \sigma} (f^\dagger_{i \sigma} b_i f_{j \sigma} + \text{h.c.}) + J \sum_{\langle ij \rangle} \mathbf{S}_i \cdot \mathbf{S}_j + \sum_i a_{0i} (f^\dagger_{i \sigma} f_{i \sigma} + b_i^\dagger b_i - 1)
$$

where $\mathbf{S}_i = f^\dagger_{i \sigma} \mathbf{S} a_{i \beta} f_{i \beta}$. The $a_{0i}$-field is a Lagrange multiplier enforcing the local occupancy constraint, and acts as a fluctuating scalar potential for the spinons and holons. Among the mean field theories proposed to decouple the quartic terms in Eq. (2), a candidate for the normal state near optimal doping is the uniform resonating-valence-bond (RVB) ansatz: $\sum_{\langle ij \rangle} (f^\dagger_{i \sigma} f_{j \sigma}) = \xi e^{i\alpha_{ij}}$. This incorporates short-range antiferromagnetic correlations without any long-range Néel order. The Lagrangian of this RVB phase can be written as:

$$
\mathcal{L} = \sum_{i,\sigma} f^\dagger_{i \sigma} (\partial_\tau - \mu_F + a_{0i}) f_{i \sigma} + \sum_i b^\dagger_i (\partial_\tau - \mu_B + a_{0i}) b_i - \frac{J}{2} \sum_{\langle ij \rangle} (e^{i\alpha_{ij}} f^\dagger_{i \sigma} f_{j \sigma} + \text{h.c.}) - t_0 \xi \sum_{\langle ij \rangle} (e^{i\alpha_{ij}} b_i^\dagger b_j + \text{h.c.})
$$

where

$$
\mathbf{a}_{ij} = \mathbf{a}_{ij} + i \theta_i + \theta_j
$$

The vector potential $a_{ij}$ arises from the fluctuations in the phase of the RVB order parameter. Longitudinal fluctuations of the gauge field $a_{ij}$ do not affect the Lagrangian due to an internal U(1) gauge symmetry:

$$
\begin{align*}
 f_i &\rightarrow f_i e^{i\theta_i} \\
 b_i &\rightarrow b_i e^{i\theta_i} \\
 a_{ij} &\rightarrow a_{ij} - \theta_i + \theta_j
\end{align*}
$$
We will therefore work in a fixed gauge, such as the Coulomb gauge, and consider only the fluctuations in the transverse part of the gauge field $a_{ij}$. In other words, we will consider only fluctuations in the internal magnetic and electric fields which are gauge-invariant quantities.

Since we are interested in the charge degrees of freedom, we wish to consider an effective theory with bosons only, and regard the spinon fluid as a medium through which the gauge field propagates. The gauge field has no dynamics in vacuo. The response of the spinon fluid to the gauge field is responsible for the dynamics of the gauge field as seen by the holons. More specifically, we can obtain the Gaussian fluctuations of the $a$-fields by treating the spinon response in the random-phase approximation. The effective gauge-field propagator is:

$$S_G = \frac{1}{2\beta L^2} \sum_{k,\omega_n} \Pi^{00}(k,\omega_n) a_0^*(k,\omega_n) a_0(k,\omega_n)$$

$$+ \frac{1}{2\beta L^2} \sum_{k,\omega_n} \Pi^\perp(k,\omega_n) a_\perp^*(k,\omega_n) a_\perp(k,\omega_n),$$

where $\beta = 1/T$, $\omega_n = 2\pi n T$, $L$ is the linear size of the system, and $a_\perp$ is the transverse part of the gauge field. (We use units where distance is measured in terms of the lattice spacing and $k_B = \hbar = e = 1$.) Here, for small $k$ and $\omega_n$, $\Pi^{00} \simeq \rho_F$, the spinon density of states at the Fermi level. This describes the Thomas-Fermi screening of internal electric fields by the fermions. The effective interaction mediated by the screened $a_0$-field is a repulsion between the bosons (of range $\propto \rho_F^{-1/2}$), consistent with the original hard-core requirement for the flux bosons. We will model this with an on-site repulsion energy, $U$. On the other hand, the magnetic fields due to fluctuations in $a_{ij}$ are not effectively screened out by the fermions. The gauge-field fluctuations as experienced by the holons are therefore strong. More specifically, the Gaussian fluctuations have the correlation function $D(k,\omega_n) = \langle a_\perp^*(k,\omega_n) a_\perp(k,\omega_n) \rangle$, given (in the continuum limit) by:

$$D(k,\omega_n) = \frac{1}{\Pi_\perp(k,\omega_n)} = \frac{1}{\gamma |\omega_n|/k + \chi k^2},$$

where $\chi$ is the orbital susceptibility of the spinon fluid and $\gamma$ is a Landau damping coefficient. These gauge-field fluctuations cause profuse forward scattering of the bosons. We believe that this is the dominant scattering mechanism in this problem. Since it is overdamped at long wavelengths with a relaxation rate which diverges as $1/k^3$, we will ignore the slow relaxation and work in a “quasistatic” limit for the gauge fields:

$$D(k,\omega_n) \to D(k,\omega_n = 0) \delta_{n,0} = \delta_{n,0}/\chi k^2.$$  

(On a square lattice, $k^2$ is replaced by $1 - (\cos k_x - \cos k_y)/2$.) This quasistatic approximation is justified when the gauge field relaxes on a time scale longer than $1/T$. Since the typical scattering wavevector of interest is the inverse deBroglie wavelength of the bosons, the relevant relaxation time scales as $1/k^3 \sim 1/T^3/2$. One might therefore expect that this approximation is valid at a sufficiently low temperature.

One might object that arguments above are based on a weak-coupling theory of the response of the spinons to the gauge fields. However, we believe that the essential features remain correct in general, namely a separation of times scales between the relaxation of the gauge fields and the boson dynamics, as well as the magnitude of the gauge fluctuations being controlled by the spinon diamagnetic susceptibility $\chi$.

The gauge-field correlator corresponds to a spatially uncorrelated flux distribution with the correlation function:

$$\langle \Phi_r \Phi_r' \rangle = \frac{T}{\chi} \delta_{r,r'},$$

where $\Phi_r = (\Phi_0/2\pi) \sum_{i} a_{ij}$ (oriented sum around the links of plaquette $r$) is the flux through plaquette $r$. ($\Phi_0 = hc/e$ is the flux quantum.) Since we are treating the thermodynamics for the gauge field classically, we have a thermal factor of $T$ in Eq. (8) for the flux variance $\langle \Phi^2 \rangle$. Given that the fermion orbital susceptibility is roughly constant at low temperatures, we might expect the flux variance to have a linear temperature dependence. However, a lattice calculation by Hlubina et al. has indicated that the Gaussian fluctuations are sufficiently strong that the flux through a plaquette is of the order of the flux quantum $\Phi_0$: $\langle \Phi^2 \rangle^{1/2} \geq 0.5\Phi_0$ down to a temperature of 0.4$T$. Since the experimental superconducting $T_c$ is of the order of 0.1$T$, we expect that this regime of strong random flux is relevant to the normal state of the cuprates until one approaches the superconducting transition. In this regime, the precise value of $\langle \Phi^2 \rangle$ should not affect the behavior of the bosons, and we will focus on a large and temperature-independent flux variance when we study the transport and correlation functions of our boson system.

Another factor leading to the reduction of the flux variance at low temperature is one that has not been discussed so far, namely that the magnitude of the gauge field should also be affected by the diamagnetic response of the holons as well as the spinons, i.e., $\langle \Phi^2 \rangle = T/(\chi_{\text{spinon}}(T) + \chi_{\text{holon}}(T))$. The holon contribution dominates near an instability to Bose condensation where $\chi_{\text{holon}}$ diverges and the bosons develop a Meissner response to expel the gauge field from the system altogether. However, we will see in this paper that Bose condensation and the holon diamagnetism are strongly suppressed even below the boson degeneracy temperature. Therefore, in a wide range of temperatures above the superconducting $T_c$, we are justified in neglecting this feedback effect of the holons on the magnitude of the gauge field fluctuations.

We can now define more precisely the effective model which we study in the rest of the paper. It is a model of
lattice bosons interacting with a quasistatic gauge field, described by effective action $S = S_B + S_G$:

$$S_B = \int_0^\beta \left( \sum_i b_i^\dagger (\partial_\tau - \mu) b_i - H_B(\tau) \right) d\tau$$

$$S_G = \frac{1}{2\beta L^2} \sum_k D^{-1}(k,0)|a_\perp(k,0)|^2$$

$$= \sum_r \frac{\Phi_r^2}{2(\Phi^2)}$$

with the boson Hamiltonian

$$H_B = -t \sum_{(ij)} (e^{ia_{ij}} b_i^\dagger b_j + \text{h.c.}) + \frac{U}{2} \sum_i n_i(n_i - 1),$$

where $t = t_0k \sim t_0$, $L$ is the linear size in units of lattice spacing and $U \gg t$. Note that, on performing the average over the gauge field, we average over static configurations only, i.e., $\{a(k, \omega_n \neq 0) = 0$.

We cannot say that we have rigorously derived above effective action from the slave-boson mean field theory of the $t$-$J$ model. Many approximations have been introduced to obtain this simple model with few adjustable parameters. For example, we have neglected the temperature dependence of the RVB order parameter $\xi$ and also the gauge-field correlations of higher order. We take the point of view that we are studying a “minimal” low-energy theory which hopefully captures many of the generic features of more complicated models.

### III. PATH INTEGRAL REPRESENTATION

It is convenient to study our boson model in a first-quantized formulation. The partition function $Z$ for a system with $N$ bosons in the canonical ensemble can be written in terms of a Feynman path integral over the boson trajectories $\{x_\alpha(\tau)\}$ ($\alpha = 1, \ldots, N$):

$$Z = \frac{1}{N!} \int P(x(\beta)) D[x_1, \ldots, x_N] \times$$

$$\int DA \delta(\nabla \cdot a) e^{-S_G(a) - \sum_\alpha \int_0^\beta a \cdot \dot{x}_\alpha d\tau - S_B^0}\left(\{x\}\right)$$

where $S_B^0$ is the action for bosons in the absence of magnetic fields:

$$S_B^0 = \int_0^\beta d\tau \left( \sum_i b_i^\dagger \partial_\tau b_i - H_B^0 \right)$$

where $H_B^0$ is given by \([11]\) with $a_{ij} = 0$. In this section, we will discuss the model in the continuum limit for notational convenience. In the continuum, one would have:

$$S_B^0 = \int_0^\beta d\tau \left[ \sum_{\alpha=1}^N \frac{m_{\alpha}^2}{2} \dot{x}_\alpha^2 + \sum_{\alpha, \beta} U_{\alpha\beta}(x_\alpha(\tau) - x_\beta(\tau)) \right].$$

Particle identity is taken into account by performing the path integral over all trajectories where the set of final boson coordinates at $\{x_1(\beta), \ldots, x_N(\beta)\}$ is some permutation of the initial boson coordinates $(x_1(0), \ldots, x_N(0))$. Any such permutations can be broken down to cycles. Each cycle forms a closed loop when the imaginary-time trajectories (world lines) of a many-boson configuration are projected onto real space. At high temperatures, cycles of length 1 dominate the partition function and the system is in a non-degenerate classical regime. At temperatures below the degeneracy temperature of the bosons, particles can travel large distances in the imaginary time, forming many ring exchanges (see Fig. 3).

In this formulation, we may integrate out the Gaussian fluctuations of the gauge field in $S_G$. Thus, we arrive at a boson-only effective theory which we study numerically in this work. The system is described by the partition function $Z = \int D\chi e^{-S_{\text{eff}}}$ where the effective action is given by:

$$S_{\text{eff}} = S_B^0 + S_2$$

with

$$S_2 = \frac{1}{2} \sum_{\alpha, \beta} \int_0^\beta \int_0^\beta \int_0^\beta \tilde{D}(x_\alpha(\tau) - x_\alpha(\tau')) \tilde{x}_\alpha \cdot \tilde{x}_\alpha d\tau d\tau'$$

where $\tilde{D}(x) = (1/\beta L^2) \sum_{k \neq 0} D(k,0)e^{-ik \cdot x}$. Note that the $k = 0$ contribution has been excluded in the sum over $k$, corresponding to a gauge choice where the $k = 0$ part of $a$ is zero. This is one way to fix the remaining degree of gauge freedom which is not determined by the condition of $\nabla \cdot a = 0$. If we consider a system with periodic boundary conditions in space, another scheme would be to fix the line integral of the gauge field around a specified path which wraps around the boundary. However, the latter scheme is inconvenient for our purposes because it breaks translational invariance explicitly.

The current interaction $D(x)$ mediated by the gauge field is logarithmic at large distances, and is attractive between opposite currents. Due to the quasistatic nature of the gauge fields, the interaction is also infinitely
retarded in time. We will see in the next section that this encourages world lines to retrace themselves, with important consequences for the boson dynamics.

Before proceeding to discuss the physical consequences of the current interaction $S_2$, some remarks about our averaging procedure for the gauge fields are in order. We have performed an “annealed” average over the gauge fields, rather than a “quenched” average. Annealed averaging is necessary in our case because our gauge field $a$ is an internal thermodynamic variable. Formally, we evaluate observables $\langle O \rangle$ as:

$$\frac{1}{Z} \int \mathcal{D}x e^{-S_{\text{tot}}} = \frac{\int \mathcal{D}x \mathcal{D}a \, P[a] \, O \, e^{-S_{\text{eff}} - i \sum \mathbf{a} \cdot dx}}{\int \mathcal{D}x \mathcal{D}a \, P[a] \, e^{-S_{\text{eff}} - i \sum \mathbf{a} \cdot dx}}$$

where $P[a] = \mathcal{N}^{-1} \delta(\nabla \cdot a) e^{-S_0[a]}$ is the probability distribution for the gauge field, and $\mathcal{N}$ is a suitable normalization factor. This is different from quenched averaging which would be appropriate if we dealt with a system with frozen impurities, such as a vortex glass. Quenched averaging requires the evaluation of:

$$\int \mathcal{D}a \, P[a] \left[ \frac{\int \mathcal{D}x \mathcal{D}a \, P[a] \, e^{-S_0 - i \sum \mathbf{a} \cdot dx}}{\int \mathcal{D}x \mathcal{D}a \, P[a] \, e^{-S_0 - i \sum \mathbf{a} \cdot dx}} \right].$$

The differences between quenched and annealed averaging from the point of view of perturbation (diagrammatic) theory has been addressed elsewhere.

From the point of view of the path integral Monte Carlo method, our ability to perform the annealed averaging means that we would not have to perform extensive averages over different frozen realizations of the random flux. Moreover, note that the effective action is manifestly real, and so we avoid the sign problem which occurs numerically when performing a quenched average over the gauge fields. We have studied boson densities between $n_b = 1/4$ and $1/6$. We choose an on-site interaction strength $U \geq 4t$. We follow the Monte Carlo methods of Ceperley and Pollock and Trivedi.

Each Monte Carlo step involves the reconstruction of world lines, $\{x_a(\tau)\}$, for all $N$ particles using the ideal boson propagator in a short interval in imaginary time. The on-site interaction and the current interaction $S_2$ are taken into account using Metropolis tests. To ensure quantum exchange, we may insist that each accepted configuration differs from the previous one by a pair exchange. This can be incorporated, without loss of detailed balance, as a Metropolis test. We refer readers to the original references for further details. (In evaluating the gauge field contribution $S_2$, we have also made use of a geometrical interpretation of $S_2$ which we discuss in the next section.) In the discretization of the imaginary time, we have used a small $\Delta \tau = \beta/M \leq 0.1/t$, so as to minimize the systematic error and to allow the reliable use of maximum entropy techniques to perform analytic continuation on our imaginary-time data to obtain the dynamical quantities of interest. This sets the lowest accessible temperature to $T \sim 0.1t$ for lattice sizes considered here. For studies on dynamic response to be discussed later, we have restricted ourselves to lattices of sizes up to $6 \times 6$, due to the need to obtain imaginary time correlation functions to a high accuracy. For the calculation of static properties, we have studied lattices as large as $10 \times 10$.

To summarize, we have obtained an effective theory of bosons with current interactions which are long-ranged in space and time. This model can be studied using path integral Monte Carlo methods. In the next section, we will discuss how these interactions affect the geometry of the boson world lines and hence the physical properties of the system.

### IV. EFFECT OF GAUGE FIELDS ON WORLD LINE GEOMETRY

#### A. “Brinkman-Rice bosons”

In this section, we will discuss how the current interaction $S_2$ mediated by the gauge field affects world-line geometry. On the infinite plane, there is a simple geometrical interpretation of this interaction in terms of the winding numbers of the boson world lines. The winding number $w_r$ around a plaquette $r$ is the number of times the imaginary-time world lines of all the bosons wind around the plaquette. Consider the partition function before averaging over the gauge field. The effect of the gauge field enters the partition function as the phase factor $\exp[-i \sum \mathbf{a} \cdot dx]$, in Eq. (12) over the gauge field. This phase factor can be written in terms of $w_r$: $\sum \mathbf{a} \cdot dx = \sum r w_r \Phi_r$. We can now perform the average directly over the Gaussian flux distribution instead of the gauge field distribution. We will be working with periodic boundary conditions (i.e., on a torus). This will be well-defined if we impose a constraint of zero total flux through the system. On averaging, the phase factor becomes:

$$\int d\lambda \prod_r d\Phi_r e^{-\sum_r \frac{\lambda^2}{2\Phi_r^2} \sum_r w_r \Phi_r + i \lambda \sum_r \Phi_r} \propto e^{-S_2}$$

$$S_2 = 2\pi^2 \left( \frac{\Phi_r^2}{\Phi_0^2} \right)^2 \left[ \sum_r w_r^2 - \frac{1}{L^2} \left( \sum_r w_r \right)^2 \right]$$

Thus we see that the action cost due to the current interaction is proportional to a geometrical property of the world lines, similar to an unoriented area, which has been termed the “Amperean area”.

$$A_\alpha = \left[ \sum_r w_r^2 - \frac{1}{L^2} \left( \sum_r w_r \right)^2 \right]$$
This geometrical interpretation of $S_2$ is particularly useful in the numerical evaluation of this quantity.

If we are working with periodic boundary conditions, the geometrical definition of $w_r$ given above will not work because there is an ambiguity in identifying which plaquettes are inside or outside a loop on a torus. Nevertheless, we can still use the above analysis for paths which do not wrap around the boundaries. (We will discuss wrapping paths in the next section.) The only modification is that we need a definition of the winding numbers which preserves Stokes’ theorem: $\oint a(x) \cdot dx = \sum_r w_r \Phi_r$.

In the case of zero total flux, a suitable definition is: $w_r = \Phi^{-1} \oint [a^0_r(x) - \text{const}] \cdot dx$, where $a^0_r(x)$ is the vector potential at $x$ due to a test flux $\Phi$ placed at plaquette $r$, and $\text{const}$ is an arbitrary reference plaquette. Geometrically, this picks $\text{const}$ to be on the “outside” of any loop on the torus. The Amperean area as defined above is independent of the choice of this plaquette, because different choices amount to global changes in the winding numbers (e.g., $w_r \rightarrow w_r + 1$) and the above definition is invariant under such changes.

The effect of the gauge field on the particles is now clear. The action $S_2$ suppresses world-line loops with large winding numbers. Indeed, since $S_2$ is non-negative, it excludes all configurations with finite Amperean area in the limit of infinite ($\Phi^2$). This suppression can be related to the original problem of holes moving in a spin liquid with a slowly varying spin quantization axis. A hole moving in a loop comes back with a random phase due to the locally fluctuating spin chiralities of the spin background. The random phase can be interpreted as arising from a fictitious random flux. World-line loops that enclose large areas are strongly suppressed when averaged over random flux distribution due to the destructive interference of the random phases. Therefore, we expect that, in the presence of strong random flux, the dominant contribution to the partition function comes from a special kind of paths that do not “see” the random flux, i.e., paths where $\oint a \cdot dx = 0$. These are “retracing paths” where each traversal of a link on the lattice is replaced in the opposite direction at some point in time, and such paths have zero Amperean area.

A similar picture of retracing paths has been studied by Brinkman and Rice, who studied a single hole in a Mott insulator where the spins are treated classically. Indeed, studies of a single particle in a strong random flux have yielded a density of states nearly identical to that of the Brinkman-Rice problem. The Brinkman-Rice model gives a linear-$T$ resistivity at high temperatures ($T > t$) but a constant scattering rate of order $t$. Although we might expect this to be applicable to our model far above the degeneracy temperature of the bosons, this behavior does not extend down to the degenerate regime relevant to the present problem.

At boson densities of interest here and at low temperatures, Bose statistics and particle exchange are important; they can give rise to behavior different from the single-particle Brinkman-Rice result. We shall look at the effect of the gauge field on the quantum exchanges among bosons more carefully in section IV-c. For now, we point out that, even in the presence of strong gauge-field fluctuations, the bosonic nature of the particles cannot be ignored because the particles can form long exchange cycles that retraces themselves so that an individual boson does not have to retrace its own path. This is an important consideration at low temperatures where the imaginary-time paths are long allowing for a strong degree of particle exchange. Although the system can be highly degenerate at low temperatures, we shall now argue that these “Brinkman-Rice bosons” remain normal at all finite temperatures, due to interactions with the fluctuating gauge fields.

### B. Destruction of superfluidity

We will now discuss the effect of the gauge field fluctuations on the superfluidity of the Bose system. We will see, as in the previous section, that this can be understood in terms of the geometrical properties of the boson world lines.

A neutral Bose system with short-range interaction in two dimensions is a superfluid below Kosterlitz-Thouless temperature $T_{KT}$. The onset of superfluidity at $T_{KT}$ is caused by the binding of vortex-antivortex pairs in the Bose fluid so that vortex motion does not cause phase slips across the system. An essential ingredient of the existence of the superfluid phase is a long-range logarithmic attraction between the vortices and the antivortices. A single vortex costs infinite energy in an infinite system $E_v = \pi \rho_s / a$ where $a$ is a short distance cutoff (vortex core radius) and $\rho_s$ is the superfluid density. Therefore single vortices cannot exist at low temperatures. Nevertheless, the proliferation of free vortices is possible above $T_{KT}$ because this provides a gain in entropy which also scales as $\log L$. However, in a charged Bose system, screening currents causes the vortex interaction to be short-ranged. In our problem, the vortex interaction becomes exponentially weak at distances beyond $\lambda_P = [T/2\rho_s t(\Phi^2)^2]^{-1/2}$, which can be interpreted as a penetration depth of the Bose fluid. Now, the creation of a single vortex costs a finite amount of energy $E_v = (\pi \rho_s / m) \log(\lambda_P/a)$. This no longer compensates the entropic gain from vortex-antivortex unbinding, and so we do not expect to see a sharp phase transition of the Kosterlitz-Thouless type at finite temperatures.

One might still expect that there is a crossover temperature scale below which the vortex density will be sufficiently low that the Bose system would have strong diamagnetic response. A rough estimate of this temperature scale using a Boltzmann weight for the vortex density gives a large value for this crossover temperature $\lambda_P$. However, we will see later that, in the presence of strong gauge fluctuations, the diamagnetic response of the bosons re-
mains small.

To understand the suppression of superfluidity specifically in our model, we turn to the path-integral formulation of the problem with periodic boundary conditions (i.e., on a torus). Ceperley and Pollock have shown that superfluidity is associated with the existence of long world-line cycles which wrap around the torus. The superfluid density is given by

$$n_s = \frac{\langle \mathbf{W}^2 \rangle}{4\pi t}$$

where $W_x$ ($W_y$) is the number of times the boson world lines wrap around the torus in the $x$ ($y$) direction. In other words, $\mathbf{W} = \sum_{\alpha=1}^{N} \int_0^\beta d\tau \mathbf{x}_\alpha/L$. In the presence of gauge fields, superfluidity is destroyed by the same mechanism that causes the Brinkman-Rice behavior: wrapping configurations pick up random phases, and should be suppressed by destructive interference on averaging over the gauge field. The number of plaquettes whose random fluxes contribute to the phase picked up by a wrapping path should increase with increasing system size. For a large enough system, one might expect this phase to be totally random. We therefore expect this suppression to be very strong. For instance, one can evaluate $S_2$ for a straight-line path which wraps around the torus in the $y$-direction. To do so, we use Eq. (16) instead of Eq. (19) because the geometrical interpretation of $S_2$ in terms of winding numbers is not applicable for wrapping paths. We find that such a path gives

$$S_2 = \frac{W_z^2}{2\beta} \sum_{k_x \neq 0, k_y = 0} D(\mathbf{k},0) \simeq 2\pi^2 W_y^2 L^2 \langle \Phi^2 \rangle / \Phi_0^2.$$

To compute $S_2$ for a more general path with wrapping $W_y$, one can break it down into a wrapping path with the same wrapping number and a non-wrapping path (Fig. 2). $S_2$ will consist of the contributions of the wrapping paths and non-wrapping paths separately, as well as a cross-term between the two paths.) We argue that $S_2$ diverges for all wrapping paths in the thermodynamic limit, and so superfluidity is destroyed at all finite temperatures.

With periodic boundary conditions, this model allows an arbitrary Aharonov-Bohm (AB) flux through the torus. This flux is related to the phase of the product of RVB parameters ($\xi_{ij}$) along a (Wilson) loop which wraps around the torus. If we average over this AB flux assuming a uniform distribution, we would find that all wrapping paths are strictly prohibited and $n_s = 0$ at all temperatures even for samples of finite size. We will not impose such a drastic condition on the wrapping paths in this work.

We can also ask whether long-range order exists in the Green’s function for the bosons. The Green’s function itself ($\langle b^\dagger(\mathbf{r})b(0) \rangle$) is not gauge invariant, and would vanish on averaging over different gauges. However, we can study the Green’s function in a fixed gauge, for example the transverse gauge $\nabla \cdot \mathbf{a} = 0$. In fact, one can write a gauge-invariant analogue correlation function which coincides with the Green’s function in the transverse gauge:

$$G(\mathbf{r}) = \langle b^\dagger(\mathbf{r})b(0) \rangle_{\nabla \cdot \mathbf{a} = 0} = \langle b^\dagger(\mathbf{r})b(0)e^{-i\int dr'f(r')\nabla \cdot \mathbf{a}(r')} \rangle$$

where $\nabla^2 f(r') = \delta(r' - r) - \delta(r')$. In the path-integral representation, the evaluation of $G$ involves a world line originating at site $\mathbf{r}$ and a world line terminating at site $0$ at the same point in imaginary time. Note that this quantity coincides with the Green’s function in the Coulomb gauge. Consider now the phase factor $\sum_\alpha \int \mathbf{a} \cdot d\mathbf{x}_\alpha$ picked up by the world lines $\{\mathbf{x}_\alpha\}$ in the evaluation of the Green’s function $G(\mathbf{r})$ in this gauge. The random flux $\Phi_\mathbf{R}$ at a distant plaquette $\mathbf{R}$ with $R > \mathbf{r}$ has a contribution of magnitude $\Phi_\mathbf{R}/R$ to the vector potential at a point $Q$ near 0 and $\mathbf{r}$. The sum of the contributions to the vector potential at $Q$ due to the random fluxes at radius $R$ from the origin is a random vector with a mean squared magnitude of $2\pi R \times (\langle \Phi^2 \rangle / R^2) \sim (\Phi^2) / R$. This analysis is valid for all fluxes which are at a distance $R > r$. Integrating over the contribution of such fluxes, the variance of the magnitude of the vector potential at $Q$ scales as $\langle \Phi^2 \rangle \log(\Lambda/\mathbf{r})$. Summing over all $Q$ near 0 and $\mathbf{r}$, we obtain a random phase with a divergent variance: $\langle \Phi^2 \rangle r^2 \log(\Lambda/\mathbf{r})$. Thus, averaging over the distant fluxes for these sites, one obtains a suppression factor of $\exp[-(\Phi^2)r^2g(r/L)]$ where $g(x) \sim \log 1/x$ for small $x$. This can be interpreted as a binding potential for the end points of $G(\mathbf{r})$. We therefore do not find long-range order in this quantity because of the destructive interference of the random phases due to distant fluxes.

We will now present numerical evidence for the suppression of superfluidity below the degeneracy temperature $T_{D0}$ of the system. A measure of the degeneracy temperature is the Kosterlitz-Thouless temperature of the system at zero flux. We make use of the observation of Ceperley and Pollock that the probability of bosons to participate in the multi-particle exchange is about $1/4$ at Kosterlitz-Thouless transition. In other words, the probability $P_1$ that a boson is in an exchange cycle of length 1 is about $1/4$. We estimate that, for our lattice bosons with density $n_b = 0.25$ and on-site inter-
action $U = 4t$, the degeneracy temperature $T_{D0} = 1.1t$. (For strong on-site repulsion, $T_{D0}$ is not particularly sensitive to the value of $U$, e.g., $T_{D0} = 0.9t$ for $U = 10t$.)

We have measured, using Eq. (21), the superfluid fraction $n_s/n_b$ at $T = t/6$ with $U = 4t$ for a range of flux variances and for systems up to $8 \times 8$ in size (Fig. 3). We see that the superfluid fraction decreases with increasing system size. In fact, the superfluid fraction as a function of $n_s$ vs. $n_b$ indicates that the scattering by gauge fields is a relevant perturbation at finite temperature. We find that different cycles retrace each other’s paths. (See Fig. 4(c).) This should slow down the imaginary-time motion of the bosons as well as reduce the probabilities for exchange. We find that this is indeed the case.

We first look at the exchange probabilities $P_i$ of a particle participating in an exchange cycle of $i$ bosons. As before, we may deduce a degeneracy temperature $T_D$ from the probability $P_i$ for a particle to be involved in particle exchange. This degeneracy temperature is reduced compared to the case of zero flux. For $U = 4t$ at quarter filling, we find that the zero-flux degeneracy temperature $T_{D0} = 1.1t$ is reduced to $T_D = 0.5t$ at $\langle \Phi^2 \rangle = 0.5 \Phi_0^2$. At $\frac{1}{8}$-filling, it is reduced from $T_{D0} = 0.8t$ to $T_D = 0.34t$. A finite $T_D$ does not imply Bose condensation at a finite temperature. Indeed, one cannot induce a superfluid transition by examining the exchange probabilities. Remarkably, in the degenerate regime below $T_D$, the exchange probabilities for the cases of $\langle \Phi^2 \rangle = 0$ and $0.5 \Phi_0^2$ are nearly identical (see Table I). In this temperature regime, a particle is equally likely to participate in an exchange cycle of any size: $P_1 \approx P_2 \approx \ldots \approx P_N \approx 1/N$.

C. World line geometry in the normal phase

Having established that our system remains normal at low temperatures, we will now examine the geometry of the world lines in this normal phase in the presence of strong gauge fluctuations. In particular, we will look at the effect of the gauge fields on quantum exchange and imaginary-time diffusion. These are mutually related: imaginary-time diffusion over large distances aids quantum exchange among particles and quantum exchange facilitates imaginary-time diffusion. For example, in a dissipative model of bosons coupled to external heat bath, a slow logarithmic imaginary-time diffusion is expected to suppress quantum exchange very strongly, resulting in an incoherent liquid even at zero temperature. In our case, the bosons are elastically scattered by the gauge fields. We find that the gauge fields have less dramatic effects on quantum exchange and imaginary-time diffusion.

We have shown that the world lines retrace themselves in the presence of random flux. One might expect that, compared with the case of zero flux, this would reduce the distance traveled by the particles in the imaginary-time interval $\beta$ before their paths must return to some permutation of their starting positions. This should slow down the imaginary-time motion of the bosons as well as reduce the probabilities for exchange. We find that this is indeed the case.

We can gain a qualitative understanding of the low-temperature exchange probabilities, by examining how the suppression of Amperean area by $S_2$ affects the geometry of the world-line configurations. When there is significant quantum exchange, individual bosons do not have to retrace their own paths in order to minimize the total Amperean area of the world-line configuration of all the bosons. Instead, one might minimize the Amperean area of each world-line loop formed by several bosons in the same exchange cycle. We find that this is not the entire situation at sufficiently low temperatures. Below $T_D$, the different world-line loops have strong overlap. We find that different cycles retrace each others’ paths (See Fig. 4). Thus, although the gauge fields have a drastic effect on the total area enclosed by all the boson world lines, individual world-line cycles may enclose large areas. One might therefore expect that some aspects of the world-line geometry, which are insensitive to the total area, may indeed be very similar to the case of zero flux.
The observation that individual particles do not have to retrace their own paths suggests that they could diffuse a greater distance than in the single-particle case. One should see a reduction in the kinetic energy \( \langle K \rangle \) of the particles compared to the Brinkman-Rice theory. This is indeed the case. (See Appendix for a discussion of the measurement of the kinetic energy.) A single particle with retracking paths has a band edge at \(-2\sqrt{3}t\) rather than \(-4t\). In our system, the kinetic energy per particle goes below the Brinkman-Rice band edge at low temperatures, approaching \(-4t\) roughly linearly in temperature (Fig. 5). Thus, we see that the strong gauge fluctuations do not have a large effect on some aspects of the world-line geometry (e.g., exchange probabilities) while having a dramatic influence on others (e.g., superfluidity).

Let us now examine the imaginary-time motion of the particles in more detail. Ideal bosons are diffusive in imaginary time at all temperatures, i.e., the mean-squared displacement of particle \( \alpha \) is linear in imaginary time \( \tau \): \( R^2(\tau) = \langle (x_\alpha(\tau) - x_\alpha(0))^2 \rangle = 4\tau t \) for \( 0 < \tau < \beta/2 \). With repulsive interactions, there is an increase in the effective mass of the particle, e.g., for \( U = 4t \) at quarter filling, we find \( t \to t^* = 0.95t \). In the presence of random magnetic flux, the imaginary-time diffusion is slowed down, and the mean-squared displacement \( R^2(\tau) \) is no longer linear in \( \tau \) at all temperatures. Fig. 6 shows our results for the (superfluid) zero-flux case at temperature \( \beta t = 9 \) and the case of strong random flux at \( \beta t = 4, 6, 9 \). Since we are working with periododic boundary conditions, we have used the definition:

\[
R^2(\tau) = \langle \left[ \int_0^{\beta/2} x_\alpha(\tau)d\tau \right]^2 \rangle .
\]

We can see that, whereas \( R^2(\tau) \) has significant downward curvature at \( \beta t = 2 \), it becomes closer to diffusive behavior as the temperature is lowered. However, we are unable to reach the asymptotic regime where the particle has traveled far on the scale of the interparticle spacing over a time period of \( \beta/2 \) (see Fig. 6 inset).

![Figure 6](image_url)

**FIG. 6.** Single-particle diffusion \( R^2(\tau) = \langle (x(\tau) - x(0))^2 \rangle \) in imaginary time for \( 0 < \tau < \beta/2 \). Solid lines: strong random flux with \( \langle \Phi^2 \rangle = 0.5\Phi_0^2 \) at \( \beta t = 4, 6, 9 \). Dashed line: zero flux at \( \beta t = 9 \). Inset: \( R^2(\beta/2) \) for zero flux (○) and \( \langle \Phi^2 \rangle = 0.5\Phi_0^2 \) (□); dashed line marks the squared interparticle spacing.

In order to study the long-time behavior, we can examine the size of the world-line exchange cycles. A cycle where the world lines of \( l \) particles \( \{x_1, \ldots, x_l\} \) form a loop can be roughly regarded as a particle traveling over a time interval of \( l\beta \). Thus, the possibility of exchange means that a world-line cycle can travel large distances compared with an individual boson. In a system with periododic boundaries, the size \( R_l \) of the cycle is defined by:

\[
R_l^2 = \left\langle \left[ \int_0^{\beta/2} \dot{x}_{l+1} d\tau + \sum_{\alpha=1}^{(l-1)/2} \int_0^\beta \dot{x}_\alpha d\tau \right]^2 \right\rangle, \quad l \text{ odd},
\]

\[
R_l^2 = \left\langle \left[ \sum_{\alpha=1}^{l/2} \int_0^\beta \dot{x}_\alpha d\tau \right]^2 \right\rangle, \quad l \text{ even.} \tag{24}
\]

For ideal bosons, \( R_l^2 \) should equal \( R^2(\tau = l\beta/2) \) at inverse temperature \( l\beta \), and therefore should scale linearly with \( l \). Fig. 6 shows \( R_l^2 \) for a 4×4 lattice with 9 particles. We have measured only cycles which do not have a net wrapping number around the periododic boundaries so that we do not have contributions from cycles with different topologies. We see that \( R_l^2 \) is linear in \( l \) for the cases of zero flux and strong random flux, although the slope of the case with the strong random flux is reduced substantially. This demonstrates that the imaginary-time motion of the bosons is diffusive at long distances.

These results indicate that we are probing an unconventional phase of a Bose liquid. Although the system remains normal, many aspects of the imaginary-time motion of the particles in the degenerate regime resemble that of a neutral Bose liquid which is a superfluid in such temperatures. In subsequent sections, we shall study the physical properties of this “strange metal” and discuss...
the relevance to the normal state of the cuprate superconductors.

### V. TRANSPORT AND OPTICAL CONDUCTIVITY

In this section, we will present our quantum Monte Carlo (QMC) results on longitudinal transport for this strange Bose metal. To obtain the conductivity of the system, we measure its imaginary-time analogue $\sigma_{\alpha\beta}(i\omega_n)$ in our quantum Monte Carlo simulation:

$$
\sigma_{\alpha\beta}(i\omega_n) = \frac{1}{|\omega_n|} \Pi_{\alpha\beta}(i\omega_n)
$$

(25)

$$
\Pi_{\alpha\beta}(i\omega_n) = \int_0^{\beta} \langle j_{\alpha}^{a}(\tau) j_{\beta}^{a}(0) \rangle e^{i\omega_n \tau} d\tau,
$$

(26)

where $j_{\alpha}(\tau) = \sum_{\tau} j_{\alpha}(\tau) e^{i\eta_{\alpha}\tau}$ and $j_{\alpha}(\tau) = \sum_{\alpha} \delta(\tau-x_{\alpha}(\tau)) \frac{d\alpha}{d\tau}$ is the gauge-invariant current (Fig. 3).

![Graph](image2)

**FIG. 8.** Current correlation function $\Pi_{xx}(i\omega_n)$ for a 6×6 lattice with 9 bosons with $\langle \Phi^2 \rangle = 0.5\Phi_0^2$ and $U = 4t$.

The imaginary-time measurements are related to the real-time conductivity $\sigma(\omega) \equiv \sigma_{xx}(\omega)$ by:

$$
\frac{1}{2L^2} \langle j_{\|}(0) \cdot j_{\perp}(0) \rangle = \int_{-\infty}^{\infty} \frac{\omega e^{-\omega\tau} \sigma(\omega)}{1 - e^{-\beta \omega}} d\omega.
$$

(27)

Deducing dynamical properties (such as conductivity) from imaginary-time data is in general an ill-posed problem. Several approximate methods are often used in the context of QMC studies. A simple method, which has been used in the study of the superfluid-insulator transition[8,9], is to fit $\sigma(i\omega_n)$ to a simple functional form, such as the Drude form $\sigma(i\omega_n) = \sigma_0/(1 + |\omega_n|/\tau_f)$. More generally, one can use a Padé approximant to fit an arbitrary number of poles and zeroes:

$$
\sigma(z) = \frac{a_0 + a_1 z + \ldots + a_N z^N}{b_0 + b_1 z + \ldots + b_N z^N}.
$$

(28)

This approach is particularly suitable if the scattering rate $1/\tau_f$ (or the position of the pole closest to the origin in Eq. (28)) is large compared to the temperature at low temperatures. This is however not the case in our problem. In our system, $\Pi_{xx}(i\omega_n)$ is nearly constant as a function of $n$ for finite $n$ even at low temperatures, suggesting that $1/\tau_f$ is proportional to $T$. (Note that $\Pi_{xx}(n=0)=0$ in the limit of strong random flux because paths which wrap around the torus are strongly suppressed.)

We have calculated the conductivity by numerical analytic continuation using the maximum-entropy (MaxEnt) method[10]. Eq. (27) takes the form of a linear integral equation:

$$
d(\tau) = \int K(\tau,\omega)r(\omega) d\omega,
$$

(29)

where $K(\tau,\omega)$ is the kernel relating the imaginary-time data $d(\tau)$ to the corresponding response function $r(\omega)$. In our QMC simulations, $d(\tau)$ is measured at discrete points $\tau = l \Delta \tau$ with mean $\langle \tilde{d} \rangle$. The errors for the time points $l$ and $m$ are correlated with a covariance matrix $C_{lm} = \langle \langle \tilde{d}_l - \langle \tilde{d} \rangle \rangle \langle \tilde{d}_m - \langle \tilde{d} \rangle \rangle \rangle$. The MaxEnt method finds an estimate of $r(\omega)$ as the function $\hat{r}(\omega)$ which maximizes the functional:

$$
\phi[\hat{r}(\omega); \alpha] = -\frac{1}{2} \chi^2 + \alpha S,
$$

(30)

where $\chi^2$ is the goodness of fit

$$
\chi^2 = \sum_{l,m} (D_l - \langle \tilde{d}_l \rangle) [C^{-1}]_{lm} (D_m - \langle \tilde{d}_m \rangle)
$$

(31)

with $D_l = \int d\omega K(\tau_l,\omega)\hat{r}(\omega)$, and the “entropy” $S$ is measured with respect to a given default model (or measure) $m(\omega)$:

$$
S = \int d\omega \left[ \hat{r}(\omega) m(\omega) - \hat{r}(\omega) \log \frac{\hat{r}(\omega)}{m(\omega)} \right].
$$

(32)

The variable $\alpha$ in Eq. (30) is a regularization parameter controlling the competition between the smoothness and
the goodness of the fit, and $\phi$ is also maximized with respect to it. We have chosen the default model $m(\omega)$ to be a constant in order not to build in any bias. Our results are not sensitive to this choice. Details of the MaxEnt method are given in Refs. 11, 12.

One can check the results of the MaxEnt inversion using relevant sum rules. In the case of conductivity, we have used the sum rule
\[ \int_0^{\infty} \sigma(\omega)d\omega = -\frac{\pi}{4} \langle K \rangle / L^2. \] (33)
which is the lattice version of the more familiar form in the continuum: $\int_0^{\infty} \sigma(\omega)d\omega = \pi n_b/2m$. In our MaxEnt results, this sum rule is obeyed to within 3% error. In order to obtain reliable data for the MaxEnt inversion, we have worked with a fine discretization in imaginary time ($t\Delta\tau \leq 0.1$). For the lowest temperatures ($T < 0.4t$), we worked at fixed $\Delta\tau$ and $\beta/L^2$. We chose $\beta \propto L^2$ to control the finite-size effects because of the imaginary-time motion of the bosons is roughly diffusive, as discussed above. Our results are in fact not very sensitive to this choice, indicating that finite-size effects are small. For instance, the values of resistivity at $\beta t = 4$ and $n_b = 1/4$ for $4 \times 4$ and $6 \times 6$ are similar within statistical error.

We find that $\sigma(\omega)$ consists of a single Drude-like peak (Fig. 9). Since this peak exhausts the sum rule $\int_0^{\infty} \sigma(\omega)d\omega = \pi n_b/2m$, its spectral weight is proportional to $-\langle K \rangle$. This spectral weight has a weak temperature dependence in this temperature range because, as already discussed, the kinetic energy approaches $-4t$ per particle as the temperature is lowered. This should be contrasted with the Brinkman-Rice result for non-degenerate particles ($T \gg t$) where the weight under $\sigma(\omega)$ decreases as $-\langle K \rangle \sim T^{-1}$.

The width of $\sigma(\omega)$ gives a transport scattering rate consistent with: $1/\tau_r = \zeta k_B T$ with $\zeta = 1.8 - 2.2$ (Fig. 10). This result has been obtained for two densities $n_b = 1/4$ and $1/6$ so that this scattering rate appears to be independent of density. Again this differs from the Brinkman-Rice result where $1/\tau_r$ is a constant of order $t$ (as one begins to see at the highest $T$ in Fig. 10). The resistivity $\rho$, given by the peak height, is consistent with a linear temperature dependence of $\rho e^2/h = (1/2\pi n_b) T/t$ for $T < 2t$ (Fig. 11). We estimate a statistical error of 5% for $\rho$ by examining fluctuations due to statistical errors in the measurement of the current correlation function. There are also systematic errors due to the smoothing of structures.

There appears to be a systematic deviation from the linear-$T$ behavior below $T = 0.3t$, in particular in the case of quarter filling. This deviation is stronger for $\rho$ than for $1/\tau_r$. The difference can be attributed to the $T$-dependence of the Drude weight discussed above which should affect the resistivity but not the relaxation time. We speculate that the deviation from linearity at the lowest temperatures may indicate the approach to zero-temperature critical behavior. This is beyond the scope of this paper.

Our resistivity agrees, to within a factor of 2, with Jaklič and Prelovšek 43 who provided an approximate diagonalization of the $t-J$ model on $4 \times 4$ lattices and...
found a Drude peak with width $2T$. They also found a broad background, and interpreted it with a frequency-dependent scattering rate $\tau(\omega)$. Indeed, some authors have interpreted the experimental optical conductivity as possessing a power-law tail and emphasized its importance. This incoherent part of the conductivity is absent from our boson model, and may be due to inelastic scattering of the bosons with the gauge field or, more generally, with the fermionic degrees of freedom.

VI. MAGNETIC RESPONSE

We now discuss the response of this degenerate Bose liquid to a weak external magnetic field perpendicular to the plane. In the absence of the random magnetic fields, a Bose liquid has a strong diamagnetic response as the temperature is lowered towards the transition to a superfluid when it develops a Meissner response. We argue here that the linear response of the system to a magnetic field is strongly suppressed by the gauge fluctuations. Qualitatively, this can be again understood by examining the world-line configurations. We have already demonstrated that the partition function is dominated by world-line paths which are unaffected by the internal gauge fields $\sum a \cdot dx_\alpha = 0$ for any $a$. These configurations are therefore also unaffected by any external magnetic fields. Thus, we see that the system has a vanishing linear response to magnetic fields in the limit of strong fluctuations. For the sake of completeness, we will now discuss more quantitatively the magnetic response of the system. Relevant physical quantities are the diamagnetic susceptibility $\chi_B$, the Hall coefficient $R_H$, and the magnetoresistance $\Delta \rho / \rho$.

Consider first the diamagnetic susceptibility. On the infinite plane, in the presence of a weak external field $H$, each world-line configuration picks up an extra factor of $\exp[-i \sum A_{\alpha} \cdot dx_\alpha] = \exp[-iH A_0]$ where $\text{curl } A_{\alpha} = H$, and $A_0 = \sum \nu_\alpha$ is the oriented area of the configuration. (In this section, we will use units where $\Phi_0 = 2\pi$.)

Expanding this in a Taylor expansion, one can write the partition function $Z(H)$ as:

$$Z(H) = \int D\{x\} \left(1 - iH A_0 - \frac{1}{2} H^2 A_0^2\right) e^{-S_{\text{eff}}}$$

$$= Z(0) \left(1 - \frac{1}{2} H^2 \langle A_0^2 \rangle\right), \quad (34)$$

where $A_0$ is the oriented area of a world-line configuration and $\langle \ldots \rangle$ denotes an average for the system at $H = 0$.

We have assumed here that the external magnetic field $H$ has negligible effect on the spectrum of the gauge fluctuations. The diamagnetic susceptibility is given by:

$$\chi_B = \frac{1}{2} \frac{\partial^2 \ln Z}{\partial H^2} = \frac{4\pi^2 T}{\Phi_0^2} \langle A_0^2 \rangle. \quad (35)$$

Since $A_o > A_0$, by definition, we can see that, when the gauge fluctuations are strong so that configurations with zero Amperean area dominate, the system has no diamagnetic response, as previously suggested in Section IV B.

It should be noted that, with periodic boundary conditions, the total flux penetrating the torus is quantized in units of the flux quantum. One would use replace $\langle A_o^2 \rangle$ by $4(\sin^2 [H_0 A_o/2]) / H_0$ where $H_0 = \Phi_0 / L^2$ is the smallest uniform field allowed in a torus of size $L$. Moreover, as in the case for the Amperean area, a geometrical interpretation of the phase factor $\int A_{\text{ext}} \cdot d\mathbf{x}$ is not possible for paths which wrap around periodic boundaries. However, these wrapping configurations are strongly suppressed in the case of strong random flux and should give negligible contribution to the susceptibility.

Magnetotransport properties can be written in terms of the conductivity tensor $\sigma_{\alpha \beta}^H$:

$$R_H \approx \sigma_{xy}^H / (H \sigma_{xx}^2) \quad (36)$$

$$\Delta \rho / \rho \approx - \Delta \sigma_{xx} / \sigma_{xx} \quad (37)$$

where $\sigma_{xx} = \sigma_{xx}^0$, and $\Delta \sigma_{xx} \equiv \sigma_{xx}^H - \sigma_{xx}^0$. To obtain the conductivity tensor, we need the current-current correlator $\langle j^\alpha(0) j^\beta(0) \rangle_H$. Expanding again in a Taylor series in $H$, one obtains the correlator:

$$\langle j^\alpha j^\beta \rangle_H = \frac{\int D\{x\} j^\alpha j^\beta (1 - iH A_0 - \frac{1}{2} H^2 A_0^2) e^{-S_{\text{eff}}}}{\int D\{x\} (1 - iH A_0 - \frac{1}{2} H^2 A_0^2) e^{-S_{\text{eff}}}}$$

$$= \frac{\langle j^\alpha j^\beta \rangle - iH \langle j^\alpha A_\beta \rangle - \frac{1}{2} H^2 \langle j^\alpha j^\beta A_\beta^2 \rangle + \ldots}{1 - \frac{1}{2} H^2 A_0^2 + \ldots} \quad (38)$$

Terms such as $\langle j^x j^y A_0^2 \rangle$ are zero by symmetry. Therefore, from (24), we get

$$\frac{\sigma_{xy}^H(\omega_n)}{H} = \frac{2\pi i}{\omega_n} \int_0^B d\epsilon \epsilon^{\omega_n - \tau} \langle j^y q = 0(\tau) j^x q = 0(0) A_\alpha \rangle$$

$$\Delta \sigma_{xx} (\omega_n) = \frac{2\pi^2}{\omega_n} \int_0^B \int_0^\beta d\tau d\epsilon^{\omega_n - \tau} \times$$

$$\left[\langle j^x q = 0(\tau) j^y q = 0(0) A_\alpha^2 \rangle - \langle j^x q = 0(\tau) j^y q = 0(0) \rangle \langle A_\alpha^2 \rangle\right]. \quad (39)$$

Since the oriented area $A_\alpha$ can be written as

$$A_\alpha = \frac{1}{2} \sum_\mathbf{r} \int_0^\beta z \cdot (j_\mathbf{r}(\tau) \times \mathbf{r}) d\tau$$

$$= \frac{1}{2} \int_0^\beta \hat{z} \cdot [\partial_\mathbf{q} \times j_\mathbf{q}(\tau)]_{\mathbf{q} = 0} d\tau \quad (40)$$

we see that we can relate this expression for the Hall conductivity $\sigma_{xy}^H$ to the more familiar one involving the average of three currents.

Again, we see that the magnetotransport response is strongly suppressed by the gauge fluctuations because it is sensitive to the oriented area of the world-line configurations. In principle, the quantities $\text{Im} \sigma_{xy}^H(\omega)$ (from which we can obtain $\text{Re} \sigma_{xy}^H(0)$ from a Kramers-Kronig
vented by on-site repulsion, at least for the moderate
sence of boson repulsion, although the instability is pre-
dense aggregates indeed occurs in our model in the ab-
tures, making the homogeneous phase unstable to col-
interactions, this effect would dominate at low temper-
will allow individual boson paths to explore a larger area
other so that their paths may retrace each other. This
gauge fluctuations. The condition of retracing paths in
stability of the homogeneous phase in the limit of strong
sion would be necessary to stabilize the uniform phase.
They further argued a long-range Coulomb repul-
densities, leading to a hole-rich phase and a hole-absent
it occurs also in the case of interacting bosons at low
the internal magnetic field.
we believe that our model illustrates
properties are generally suppressed from the classi-
properties, one may attempt to restore dynamics to the
gauge fields. If the gauge field may relax in time, then
the boson world lines no longer have to obey the con-
dition of strictly retracing paths. This would allow the
world lines to enclose a finite oriented area and hence a
finite response to external magnetic fields. However, we
emphasize that such an approach might not represent the
physics completely. We believe that our model illustrates
the general point that the influence of an external field
on the system is strongly masked by the fluctuations of
the internal magnetic field.

VII. DENSITY CORRELATION FUNCTION

A. Phase separation

Non-interacting bosons are infinitely compressible. They
would therefore collapse into a small region of the
system in the presence of any quenched disorder which
has a tail of localized states in the single-particle spec-
trum. An analogous collapse is also found in this prob-
lem with annealed random flux. Such an instability was
discussed by Feigelman et al. who have argued that
it occurs also in the case of interacting bosons at low
densities, leading to a hole-rich phase and a hole-absent
phase. They further argued a long-range Coulomb repul-
sion would be necessary to stabilize the uniform phase.

Within the world-line picture, one can visualize the in-
stability of the homogeneous phase in the limit of strong
gauge fluctuations. The condition of retracing paths in
this limit encourages the bosons to come close to each
other so that their paths may retrace each other. This
will allow individual boson paths to explore a larger area
(in imaginary time), and hence lower the kinetic energy
of the system compared to the case with each boson has
to retrace its own path. In the absence of any repulsive
interactions, this effect would dominate at low temper-
atures, making the homogeneous phase unstable to col-
lapse.

We find that this instability towards the formation of
dense aggregates indeed occurs in our model in the ab-
sence of boson repulsion, although the instability is pre-
vented by on-site repulsion, at least for the moderate
boson densities of interest here. We have studied the in-
stability by examining the compressibility of the system:
\[ \kappa = \lim_{q \to 0} \kappa(q) \]

\[ \kappa(q) = \frac{1}{Nn_b} \int_0^\beta d\tau (n_q(\tau)n_{-q}(0)) \]  

(41)

where \( n_q(\tau) \) is the Fourier transform of the boson density
at imaginary time \( \tau \). Alternatively, \( \kappa = \lim_{q \to 0} \beta S(q)/n_b^2 \)
where \( S(q) \) is the static structure factor:

\[ S(q) = \frac{1}{L^2} \langle n_q(\tau)n_{-q}(\tau) \rangle \]  

(42)

Fig. 12. Static structure factor (inset) and the \( q \)-dependent compressibility as a function of \( q \) in the \((\pi,\pi)\) direction for different values of \( U \). \( \beta t = 4 \), \( \langle \Phi^2 \rangle = 0.5\Phi_0^2 \), \( n_b = 0.25 \).

In Fig. 12 we show the behavior of \( S(q) \) and \( \kappa(q) \) for
different values of the on-site repulsion \( U \) for a \( 10 \times 10 \) lat-
tice with 25 bosons. The structure factor \( S(q) \) as a func-
tion of \( q \) is qualitatively different for the cases of small
\( U \) and large \( U \) (compared to \( t \)): \( S(q) \) for \( q = (\frac{\pi}{L}, \frac{\pi}{L}) \) is
greater than the density \( n_b \) for when the on-site inter-
action is small. We can also look at the compressibility.
Since we work with finite systems at fixed boson num-
ber, we will evaluate \( \kappa(q) \) at the smallest wavevector
of the system as an estimate of the \( q = 0 \) behavior. We see
that, in the presence of random magnetic flux, the
compressibility increases with decreasing \( U \). This can be
interpreted as a divergence as \( q \to 0 \) for small \( U \), and
hence an instability of the homogeneous phase. (This is
also reflected in the magnitude of the fluctuations in our
QMC results for \( \kappa(q) \) which grows as \( q \to 0 \) for suf-
ciently small \( U \).) However, for strong on-site repulsion,
the density correlations show no sign of an instability at
this density.

B. Static structure factor

The density fluctuations in our boson model should be
relevant to the charge fluctuations in the full \( t-J \) model.
It has been pointed out that the density excitations of the $t$-$J$ model does not resemble those of a conventional Fermi system. We will now compare our results with numerical results on the full $t$-$J$ model in the literature.

The static structure factor $S(q, \omega)$ has been calculated by various means [42]. Fig. 13 shows the static structure factor for our boson system together with that of the $t$-$J$ model [43] at $T = 0.25t$. We see that our results are qualitatively similar to the $t$-$J$ model, with improving quantitative agreement as one approaches the hard-core limit (see, for example, $U = 16t$). We should point out that this dependence on $U$ should not be as strong for the transport properties of the system, because the particle currents are not directly affected by the repulsive density interactions.

It is also interesting to note that the magnitude of the gauge field fluctuations has a relative weak effect on $S(q)$ when the on-site repulsion $U$ is strong. However, as we shall see in the next section, the dynamics of the density excitations is strongly modified by the interaction with the gauge fields.

![Graph showing static structure factor](image)

**FIG. 13.** Static structure factor of the boson model at density $n_0 = 0.2$ along the $(\pi, \pi)$ direction at $T = 0.25t$. Asterisks: $t$-$J$ model results at electron density $n = 1 - n_0 = 0.8$ and $t/J = 2$.

### C. Dynamic structure factor

We now look at the dynamic structure factor $S(q, \omega)$:

$$S(q, \omega) = \frac{1}{L^2} \int dt e^{i\omega t} \langle n_q(t) n_{-q}(0) \rangle$$  \hspace{1cm} (43)

where $n_q(t)$ is the Fourier transform of the density in real time. The dynamic structure factor is related to the imaginary-time density-density correlation function by

$$\frac{1}{L^2} \langle n_q(\tau) n_{-q}(0) \rangle = \int_0^\infty (e^{-\tau\omega} + e^{(\beta - \tau)\omega}) S(q, \omega) d\omega.$$  \hspace{1cm} (44)

Again, we use MaxEnt to perform the inversion of this integral equation. Two sum rules can be used as a check of the MaxEnt procedure.

$$\int_0^\infty d\omega (1 - e^{-\beta\omega}) \omega S(q, \omega) = -\frac{(K)}{2L^2} (2 - \cos q_x - \cos q_y) t$$

$$\int_0^\infty d\omega \frac{1 - e^{-\beta\omega}}{\omega} S(q, \omega) = \frac{1}{2} \eta^2 \kappa(q)$$  \hspace{1cm} (45)

These are lattice versions of the $f$-sum rule and the compressibility sum rule. They are satisfied within 1% error in our results.

![Graph showing dynamic structure factor](image)

**FIG. 14.** Dynamic structure factor of the superfluid phase ($\langle \Phi^2 \rangle = 0$) and the normal phase ($\langle \Phi^2 \rangle = 0.5\Phi_0^2$) in the $(\pi, \pi)$ direction. $U = 4t$, $T = t/6$ at quarter-filling.

Fig. 14 shows $S(q, \omega)$ for our bosons with and without the random flux. The system in the absence of random flux should be a superfluid at the temperature and densities considered here, and therefore should possess well-defined phonon excitations. We see sharp phonon peaks in the density excitation spectrum, for instance, at wavevector $q = (\pi/3, \pi/3)$. These long-lived phonon excitations of the superfluid phase do not survive the coherence-breaking effect of the gauge-field interactions. We find only break peaks in $S(q, \omega)$ in the presence of strong random flux.

Another effect of the presence of the gauge field is a reduction in the bandwidth of the density excitations. This might be expected because the gauge-field interaction tends to increase the compressibility of the system. Indeed, we see that the center of the $(\pi, \pi)$ peak is pulled in from $7.6t$ to $6.8t$.

We also see that the dynamic structure factor has a simple scaling with the hole density (Fig. 13): $S(q, \omega; n_h) = n_h S(q, \omega)$ holds for $n_h = 0.1 \sim 0.3$. This is natural in a model of degenerate bosons where the boson density is equal to the hole density.
We will now compare our results with numerical results on the full t-J model. It should be noted that, although we expect the electron density excitations of the t-J model to be dominated by its holon component, there is no quantitative equivalence between the structure factors of the t-J model and our boson-only model. Nevertheless, we argue that the dynamic structure factor of our model has qualitative similarities with that of the t-J model. For instance, the absence of sharp peaks in the dynamic structure factor is also found in the t-J model. An obvious similarity, built into our boson model a priori, is the lack of any structure indicating scattering across a Fermi surface at \( q = 2k_F \). Another feature is the scaling of dynamic structure factor with the hole density.

We find that \( S(q, \omega) \) along the \((\pi, \pi)\) direction agrees well with an exact diagonalization study of the t-J model at a similar hole density, as shown in Fig. 16. (We have used a moderate rescaling of the hopping energy: \( t = 0.9t_0 \) where \( t_0 \) is the hopping energy in the t-J model.) The area under \( q = (\frac{\pi}{3}, \frac{\pi}{3}) \) peak is larger in our model than in the t-J model. We believe that, as in the case of the static structure factor, this discrepancy can be improved with if we use a stronger on-site repulsion. However, the structure factor does not agree with the t-J model along the \((\pi, 0)\) direction. It might be that the spectrum of the holes at zero temperature is qualitatively different from the simple tight-binding spectrum that we have assumed here.

VIII. CONCLUSION

In summary, we have studied a degenerate Bose system which remains metallic below its degeneracy temperature due to elastic scattering with random and quasistatic gauge fields. In the path-integral picture, the bosons retrace their paths in the limit of strong gauge fluctuations in order to avoid the quantum frustration due to the fluctuating gauge field. We have demonstrated that many features of these “Brinkman-Rice bosons” indeed mimic the behavior of the full t-J model and the normal state of the cuprate superconductors. These features include the linear-\( T \) dependence of the longitudinal scattering rate and a charge excitation spectrum which consists of broad incoherent structures. This model itself has a strongly suppressed response to external magnetic fields, hinting that the behavior of the system as measured in Hall and magnetoresistance experiments have to understood in terms of a separate mechanism.

It would also be interesting to understand the behavior of the system in the zero-temperature limit. Although the limit of infinite gauge fluctuations (i.e., a uniform flux distribution on a lattice) would strictly forbid any world lines to wrap around periodic boundaries, one may consider the case of weaker gauge fluctuations in the zero-temperature limit and ask whether there is a critical value of \( \langle \Phi^2 \rangle \) below which the system is a superfluid at zero temperature. This will involve a study of the system at very low temperatures near a quantum critical point. This is beyond the scope of this paper.

We thank Wolfgang von der Linden for sending us his MaxEnt code and for many helpful correspondences. We also thank W. Putikka, R. Eder, and S. Maekawa for sending us their data for comparison. We acknowledge helpful conversations with J.T. Chalker, S.M. Girvin, D.H. Lee, E. Sorensen, X.-G. Wen, and S.C. Zhang. This work was supported by the NSF MRSEC program (DMR 94-0034), NEC (DHK) and EPSRC/NATO (DKKL).

APPENDIX A: OPERATOR AVERAGES

In this appendix, we discuss the evaluation of operator averages. In the path-integral representation of the partition function, world-line configurations are sampled according to a distribution proportional to \( \exp(-S_B^0 - S_2) \).
In our Monte Carlo scheme, we discretize the imaginary-time interval $\beta$ into $M$ segments of length $\Delta \tau$, and we define a world-line configuration by the boson coordinates at these discrete time points: $\{R_0, R_1, R_2, \ldots, R_M = P(R_0)\}$. ($R_m$ denotes the coordinates of the $N$ bosons at $m$-th time slice: $R_m = (x_1^{(m)}, \ldots, x_N^{(m)})$, and $R_M$ is a permutation of the coordinates of $R_0$.)

The configurations are sampled according to the probability:

$$P(\{R\}) = \frac{1}{N} e^{-S(\{R\})} \prod_{m=0}^{M-1} \rho_{\Delta \tau}(R_m, R_{m+1}),$$

where $N$ is a normalization constant, and $\rho_{\Delta \tau}(R, R')$ is the short-time (high-temperature) density matrix in the absence of gauge fields. It is given by:

$$\rho_{\Delta \tau}(R, R') = \langle R|e^{-\frac{1}{\beta} \Delta \tau (H_K^0 + H_U)}|R'\rangle \approx \langle R|e^{-\frac{1}{\beta} \Delta \tau H_U} e^{-\frac{1}{\beta} \Delta \tau H_K^0} e^{-\frac{1}{\beta} \Delta \tau H_U} |R'\rangle = \langle R|e^{-\Delta \tau H_K^0} |R'\rangle e^{-\frac{1}{\beta} \Delta \tau (\tilde{H}_U(R) + \tilde{H}_U(R'))} \rangle$$

with $\tilde{H}_U(R) = (R|H_U|R)$, and

$$H_K^0 = -t \sum_{\langle ij \rangle} (b_i^\dagger b_j + \text{h.c.})$$

(A3)

$$H_U = \frac{U}{2} \sum_i n_i(n_i - 1).$$

(A4)

The error involved in this approximation of the density matrix is $O(\Delta \tau^3)$.

Measurements which depend only on particle positions are simple to evaluate in this path-integral representation. The expectation value of such a measurement $O$ is given by

$$\langle O \rangle = \text{Tr} \left[ \hat{O} (R_0, R_1, R_2, \ldots) P(R_0, R_1, R_2, \ldots) \right]$$

(A5)

where $\hat{O}(\{R\})$ is the measured value for the world-line configuration $\{R\}$, and the trace is taken over all such configurations.

Averages of operators which are non-local in position space are more cumbersome to evaluate. An example is the kinetic energy:

$$\langle H_K \rangle = -t \sum_{\langle ij \rangle} \langle e^{i a_{ij}} b_i^\dagger b_j + \text{h.c.} \rangle.$$ 

(A6)

The gauge field $a_{ij}$ is defined on the link between the neighboring sites $i$ and $j$. The Peierls factor closes the gap in the imaginary-time loop caused by the action of kinetic energy operator. Inserting the operator $\hat{H}_K$ in the imaginary-time slice between the $m = 0$ and 1, it can be shown that the kinetic energy can be evaluated as:

$$\langle H_K \rangle = \text{Tr} \left[ \frac{\langle R_0| H_K^0 U_{\Delta \tau} | R_1 \rangle}{\langle R_0| H_{\Delta \tau} | R_1 \rangle} P(\{R\}) \right] = \text{Tr} \left[ \frac{\langle R_0| H_K^0 e^{-\Delta \tau H_K^0} | R_1 \rangle}{\langle R_0| e^{-\Delta \tau H_K^0} | R_1 \rangle} \times e^{\frac{i}{\beta} \Delta \tau (U_{\Delta \tau}(R_0) - U_{\Delta \tau}(KR_0)) P(\{R\})} \right]$$

(A7)

where $\tilde{H}_U(KR)$ is defined by $H_U\{H_K^0 |KR\} \equiv \tilde{H}_U(KR)\{H_K^0 |KR\}$, and $U_{\Delta \tau}$ is the short-time evolution operator:

$$U_{\Delta \tau} = e^{-\frac{1}{\beta} \Delta \tau H_U} e^{-\Delta \tau H_K^0} e^{-\frac{1}{\beta} \Delta \tau H_U}.$$
