Quantum Nature of the Big Bang

Abhay Ashtekar, Tomasz Pawlowski, and Parampreet Singh
Institute for Gravitational Physics and Geometry, Physics Department, The Pennsylvania State University, University Park, PA 16802, USA

Some long standing issues concerning the quantum nature of the big bang are resolved in the context of homogeneous isotropic models with a scalar field. Specifically, the known results on the resolution of the big bang singularity in loop quantum cosmology are significantly extended as follows: i) the scalar field is shown to serve as an internal clock, thereby providing a detailed realization of the ‘emergent time’ idea; ii) the physical Hilbert space, Dirac observables and semi-classical states are constructed rigorously; iii) the Hamiltonian constraint is solved numerically to show that the big bang is replaced by a big bounce. Thanks to the non-perturbative, background independent methods, unlike in other approaches the quantum evolution is deterministic across the deep Planck regime.

Thanks to the influx of observational data, recent years have witnessed enormous advances in our understanding of the early universe. To interpret the present data, it is sufficient to work in a regime in which space-time can be taken to be a smooth continuum as in general relativity, setting aside fundamental questions involving the deep Planck regime. However, for a complete conceptual understanding as well as interpretation of the future, more refined data, these long-standing issues will have to be faced squarely. Examples are: i) How close to the big-bang does the smooth space-time of general relativity make sense? In particular, can one show from first principles that this approximation is valid at the onset of inflation? ii) Is the big-bang singularity naturally resolved by quantum gravity? Or, is some external input such as a new principle or a boundary condition at the big bang essential? iii) Is the quantum evolution across the ‘singularity’ deterministic? In the Pre-big-bang and Ekpyrotic scenarios, for example, the answer has been in the negative. iv) If the singularity is resolved, what is on the ‘other side’? Is there just a quantum foam far removed from any classical space-time, or, is there another large, classical universe? The purpose of this letter is to summarize results from recent analytical and numerical investigations within loop quantum cosmology which address these and related issues.

Loop quantum gravity (LQG) is a background independent, non-perturbative approach to quantum gravity. Loop quantum cosmology (LQC) focuses on symmetry reduced models but carries out quantization by mimicking the constructions used in the full theory. Results to date in this area fall in two broad categories: a) Resolution of the big-bang singularity using modifications of the gravitational Hamiltonian due to quantum geometry; and, b) Phenomenological predictions from effective equations that incorporate the modifications of the matter Hamiltonians due to quantum geometry (see, e.g., [5, 6]). As in the first category, we focus on the more fundamental issues. While previous results showed that the LQC evolution does not break down at the singularity, as pointed out e.g. in [7], they did not shed light on what happened before. By constructing the missing conceptual and mathematical infra-structure, we show that the universe has a classical pre-big-bang branch, joined deterministically to the post-big-bang branch by the LQC evolution. Our detailed analysis of the Planck regime also provides tools to test the validity of assumptions underlying phenomenological predictions.

We will illustrate effects of quantum geometry on both the gravitational and matter Hamiltonians through a simple example: the spatially homogeneous, isotropic $k=0$ cosmologies with a massless scalar field. Although the approach admits generalizations, we focus on these models because a singularity is unavoidable in their classical theory. The question is if it is naturally tamed by quantum effects. The answer in the ‘geometrodynamical’ framework used in older cosmologies turns out to be in the negative. For example, if one begins with a semi-classical state representing a classical universe at late times and evolves it back via the Wheeler DeWitt equation, one finds that it just follows the classical trajectory into the big bang singularity. In LQC, the situation is very different. This may seem surprising at first. For, the system has only a finite number of degrees of freedom and von Neumann’s theorem assures us that, under appropriate assumptions, the resulting quantum mechanics is unique. However, for reasons we will now explain, LQC does turn out to be qualitatively different from the Wheeler-DeWitt theory.

Because of spatial homogeneity and isotropy, one can fix a fiducial (flat) triad $\omega^a_i$ and its dual co-triad $\omega'_a$. The SU(2) gravitational spin connection $A^a_i$ used in LQG has only one component $c$ which furthermore depends only on time; $A^a_i = c \, \omega^a_i$. Similarly, the momentum $E^a_i$ canonically conjugate to $A^a_i$ —representing a (density weighted) triad— has a single component $p$; $E^a_i = p \, (\det \omega) \, \omega^a_i$.
$p$ is related to the scale factor $a$ via $a^2 = |p|$. However, $p$ is not restricted to be positive; under $p \rightarrow -p$ the metric remains unchanged but the spatial triad flips the orientation. The pair $(c, p)$ is canonically conjugate: $(c, p) = (8\pi G \gamma/3)$, where $\gamma$ is the Barbero-Immirzi parameter.

Quantization is carried out by closely mimicking the procedure used in full LQG \textsuperscript{10}. There, the elementary variables which have unambiguous operator analogs in quantum theory are the holonomies $h$ of connections $A^a_i$ and the (smearied) triads $E^i_a$. Now, background independence leads to a surprisingly strong result \textsuperscript{11}: in essence, the basic operator algebra generated by holonomies and triads admits a unique irreducible, diffeomorphism covariant representation. In this representation, there are operators $\hat{h}$ representing holonomies and $\hat{E}$ representing (smearied) triads. But there are no operators representing connections $A^a_i$ themselves. In the cosmological model now under consideration, holonomies along a straight line of (oriented) length $\mu$ (with respect to the fiducial triad $\{e_i\}$) are almost periodic functions of $c$ of the form $N_\mu(c) := \exp(\mu e_c/2)$. (The $N_\mu$ are the analogs of spin-network functions in the full theory.) In the quantum theory, then, we are led to a representation in which operators $\hat{N}_\mu$ and $\hat{p}$ are well-defined, but there is no operator corresponding to the connection $c$ itself (because the 1-parameter group $N_\mu$ is not weakly continuous in $\mu$). This new quantum mechanics is inequivalent to the Wheeler-DeWitt theory already at a kinematical level. In particular, the gravitational part of the Hilbert space is now $L^2(\hat{R}_{\text{Bohr}}, d\mu_{\text{Bohr}})$, the space of square integrable functions on the Bohr compactification of the real line, rather than the standard $L^2(\mathbb{R}, d\mu)$ \textsuperscript{10}. While in the semi-classical regime LQC is well approximated by the Wheeler-DeWitt theory, important differences manifest themselves at the Planck scale. These are the hallmarks of quantum geometry \textsuperscript{2, 3}.

The new representation also leads to a qualitative difference in the structure of the Hamiltonian constraint operator: the gravitational part of the constraint is a difference operator rather than a differential operator as in the Wheeler-DeWitt theory. The derivation \textsuperscript{2, 10} can be summarized briefly as follows. In the classical theory, the gravitational part of the constraint is given by $\int d^{3}x \, e^{1/k} e^{-1} E^{i}_{a} F^{a}_{b} F^{b}_{c}$ where $e = \left|\det E\right|^{1/2}$ and $F^{a}_{b}$ is the curvature of the connection $A^a_i$. The part of this operator involving triads can be quantized \textsuperscript{10} using a standard procedure introduced by Thiemann in the full theory. However, since there is no operator corresponding to the connection itself, one has to express $F^{a}_{b}$ as a limit of the holonomy around a loop divided by the area enclosed by the loop, as the area shrinks to zero. Now, quantum geometry tells us that the area operator has a minimum non-zero value, $\Delta$, and in the quantum theory it is natural to shrink the loop only till it attains this minimum. There are two ways to implement this idea in detail. Here, we will use the one which has already appeared in the literature \textsuperscript{2, 3, 10} although it has certain drawbacks in the semi-classical regime, especially in more general models. The second method will be discussed in the second of the detailed papers \textsuperscript{4}, which will also show that the quantum bounce and deterministic evolution across the Planck regime persist if the second and more satisfactory method is used. In both cases, it is the existence of the ‘area gap’ $\Delta$ that leads one to a difference equation.

Let us represent states as functions $\Psi(\mu, \phi)$, where $\phi$ is the scalar field and (modulo a fixed multiple of $\ell^3_{\text{Pl}}$) the dimensionless real number $\mu$ is the eigenvalue of $\hat{p}$ \textsuperscript{10}. Then in LQC the (self-adjoint) Hamiltonian constraint is given by \textsuperscript{3}

$$
\partial^2_\phi \Psi = [B(\mu)]^{-1} \left[ C^+(\mu) \Psi(\mu + 4\mu_o, \phi) + C^o(\mu) \Psi(\mu, \phi) + C^-(\mu) \Psi(\mu - 4\mu_o, \phi) \right] = -\Theta(\Psi, \phi)
$$

where $C^+(\mu) = (\pi G/9\mu^3_o) \left| \mu + 3\mu_o \right|^{3/2} - \left| \mu + \mu_o \right|^{3/2}$; $C^-(\mu) = C^+(\mu - 4\mu_o)$; $C^o(\mu) = -C^+(\mu) - C^-(\mu)$ and where $(6/8\pi G \mu^3_o)^{3/2} B(\mu)$ are the eigenvalues of the operator $[\hat{p}]^{-3/2} \textsuperscript{10}$. The fixed real number $\mu_o$ is determined by the area gap: $(8\pi G/6) \mu_o \ell^3_{\text{Pl}} = \Delta$.

Now, in each classical solution, $\phi$ is a globally monotonically increasing function of time and can therefore be taken as the dynamical variable representing an internal clock. In quantum theory, even on-shell, there is no space-time metric. But since the quantum constraint \textsuperscript{10} dictates how $\Psi(\mu, \phi)$ ‘evolves’ as $\phi$ changes, it is convenient to regard the argument $\phi$ in $\Psi(\mu, \phi)$ as ‘emergent time’ and $\mu$ as the physical degree of freedom. A complete set of Dirac observables is provided by the constant of motion $\hat{p_o}$ and operators $\hat{\mu}_{\phi_o}$ determining the value of $\mu$ at the ‘instant’ $\phi = \phi_o$.

Physical states are the (suitably regular) solutions to Eq \textsuperscript{11}. The map $\hat{\Pi}$ defined by $\hat{\Pi} \Psi(\mu, \phi) = \Psi(-\mu, \phi)$ corresponds just to the flip of orientation of the spatial triad (under which geometry remains unchanged); $\hat{\Pi}$ is thus a large gauge transformation on the space of solutions to Eq. \textsuperscript{11}. One is therefore led to divide physical states into sectors, each providing an irreducible, unitary representation of this symmetry. As one would expect, physical considerations imply that we should consider the symmetric sector, with eigenvalue $+1$ of $\hat{\Pi}$ \textsuperscript{4}.

To endow this space with the structure of a Hilbert space, we use the ‘group averaging method’ \textsuperscript{12}. The technical implementation of this procedure is greatly simplified by the fact that the difference operator $\Theta$ on the right side of \textsuperscript{11} is independent of $\phi$ and can be shown to be self-adjoint and positive definite (on the Hilbert space $L^2(\hat{R}_{\text{Bohr}}, B(\mu)d\mu_{\text{Bohr}})$). Since $\Theta$ is a difference operator, the resulting physical Hilbert space $\mathcal{H}$ has sectors $\mathcal{H}_\epsilon$ which are superselected; $\mathcal{H} = \oplus \mathcal{H}_\epsilon$ with $\epsilon \in [0, 2\mu_o]$. States $\Psi(\mu, \phi)$ in $\mathcal{H}_\epsilon$ (are symmetric under the orientation inversion $\hat{\Pi}$ and) have support on points $\mu = \pm \varepsilon + 4n\mu_o$. Let us consider a generic $\mathcal{H}_\epsilon$ (The small technical differences in the exceptional cases are discussed in \textsuperscript{4}; they do not affect the main conclusions.) Wave functions $\Psi(\mu, \phi)$ solve \textsuperscript{11} and are of
positive frequency with respect to the ‘internal time’ \( \phi \). Equivalently, they satisfy the ‘positive frequency’ square root of Eq (1):

\[
-i\partial_\phi \Psi = \sqrt{\Theta} \Psi \tag{2}
\]

and the inner-product is given by:

\[
\langle \Psi_1 \mid \Psi_2 \rangle_{\text{phy}} = \sum_{\mu \in \{\pm i \mu_o, Z\}} B(\mu) \overline{\Psi_1(\mu, \phi)} \Psi_2(\mu, \phi), \tag{3}
\]

where as usual \( Z \) denotes the set of integers. On these states, the Dirac observables act in the expected fashion:

\[
\hat{\rho}_\phi \Psi = -i\hbar \partial_\phi \Psi \tag{4a}
\]

\[
\hat{\mu}_\phi \Psi(\mu, \phi) = e^{i\sqrt{\Theta}(\phi-\phi_o)} \mu \Psi(\mu, \phi_0) \tag{4b}
\]

One can also begin with the complete set of Dirac observables \( \Theta \) and show that \( \Theta \) is the unique inner product which makes them self-adjoint.

To construct semi-classical states and for numerical simulations, it is convenient to express physical states as linear combinations of the eigenstates of \( \hat{\rho}_\phi \) and \( \Theta \). We note that, for \( \mu > \mu_o \), there is a precise sense \( \Theta \) in which the difference operator \( \Theta \) approaches the 3 natural constructions to implement this idea in de-erevolve them numerically ‘backward in time’. There are which are semi-classical at late times —e.g., now—and evolve them numerically ‘backward in time’. There are three natural constructions to implement this idea in detail, reflecting the freedom in the notion of semi-classical states. The main results in all three cases are the same \( \Theta \). Here we will report on the results obtained using the strategy that brings out the contrast with the Wheeler DeWitt theory most sharply.

As noted before, \( \rho_o \) is a constant of motion. For the semi-classical analysis, we are led to choose a large value \( p_o^* \) \( \gg \hbar \) in the classical \( c = G = 1 \) units. In the closed model, for example, this condition is necessary to ensure that the universe can expand out to a macroscopic size. Fix a point \( (\mu^*, \phi_o) \) on the classical trajectory with \( p_\phi = p_\phi^* \) which starts out at the big bang and then expands, choosing \( \mu^* > 1 \). We want to construct a state which is peaked at \( (\mu^*, p_\phi^*) \) at the initial ‘time’ \( \phi = \phi_o \) and follows its ‘evolution’ backward. Let \( \Psi(k) \) be a Gaussian, peaked at a value \( k^* \) given by \( p_\phi^* = -\sqrt{16\pi G \hbar^2/3} k^* \). Set

\[
\Psi(\mu, \phi_0) = \int_{-\infty}^{\infty} dk \tilde{\Psi}(k) e^{i\omega(k)(\phi_o-\phi)} \tag{8}
\]

where \( \phi^* = -\sqrt{3/16\pi G \ln |\mu^*|} + \phi_o \). It is easy to verify that \( \Psi(\mu, \phi_0) \) is the desired initial data, sharply peaked at \( p_\phi = p_\phi^* \) and \( \mu = \mu^* \). If evolved using the Wheeler-DeWitt analog \( -i\partial_\phi \Psi = \sqrt{\Theta} \Psi \) of Eq (2), it would remain sharply peaked at the chosen classical trajectory and simply follow it into the big-bang singularity \( \Theta \). However, if it is evolved via (2), the situation becomes qualitatively different. The state remains sharply peaked at the classical trajectory till the matter density reaches a large critical value (which depends on \( p_\phi^* \), but then bounces, joining on to the ‘past’ portion of a trajectory which was classically headed towards the big crunch (see figures).

To ensure that these results are robust, a variety of numerical simulations were performed to integrate Eq (1) using the adaptive step, 4th order Runge-Kutta method. Due to space limitation, we will summarize only one of these. Here, we chose \( c = 2\mu_o \) and initial data with \( p_\phi^* = 10^4 \sqrt{G \hbar^2} \), \( \mu^* = 10^5 \mu_o \) and the spread in the Gaus-
FIG. 2: The expectation values of Dirac observables $\hat{p}|\phi|$ are plotted (in multiples of $\mu_0$), together with their dispersions. They exhibit a quantum bounce which joins the contracting and expanding classical trajectories marked by fainter lines.

sian $\tilde{\Psi}(k)$ given by $\Delta p_\phi/p_\phi^* = 7.5 \times 10^{-3}$, where $\Delta p_\phi$ is the uncertainty in $p_\phi$. The boundary of the numerical grid was chosen at $1.5 \mu^*$ (where $|\tilde{\Psi}(\mu, \phi_0)| < 10^{-24}$). On the boundary, Eq (2) was approximated by the Wheeler-DeWitt equation and ‘outgoing wave’ boundary conditions were imposed. Results of the evolution exhibit a quantum bounce as shown in figures 1 and 2. Away from the Planck regime the uncertainties in the Dirac observables are essentially constant.

We conclude with a few remarks.
1. The main limitation of this analysis is the restriction to homogeneity and isotropy. The approach can be readily extended to incorporate anisotropic models and potentials for scalar fields. However, incorporation of inhomogeneities has only just begun. The hope is that the deterministic evolution of LQC will enable one to evolve perturbations across the Planck regime.
2. The dramatic difference between the predictions of the Wheeler DeWitt theory and LQC can be intuitively understood through effective equations which can be derived from Eq (1) using certain approximations. One finds that quantum geometry (which is ignored in the Wheeler DeWitt theory) modifies the Friedmann equations. The modifications are significant only in the Planck regime and come with the sign required to make gravity repulsive.
3. A common feature with the early LQC papers is that we did not have to introduce new physical input such as a boundary condition at the singularity. We only asked that the quantum state be semi-classical at late times. This is an observational fact rather than a new theoretical input or a philosophical preference. However, there are also notable differences from the existing LQC literature. First, while much of the phenomenological work in LQC has incorporated quantum geometry effects only on the matter Hamiltonian, here they were incorporated also in the gravitational part. Second, we constructed the physical Hilbert space, Dirac observables and semi-classical states, thereby extracting physics of the Planck regime, going significantly beyond the demonstration of singularity resolution. Specifically, our results show that the quantum geometry in the Planck regime serves as a ‘quantum bridge’ between large classical universes, one contracting and the other expanding. Finally, the idea that the scalar field can be used as an internal clock has appeared before, especially in [13]. However, that analysis used conventional quantum mechanics rather than the Bohr compactification which descends from full LQG. Our final physical Hilbert space is also different; it’s construction is not motivated by the Kodama state.
